Chapter 1

Introduction

Before we start with the subject of this notes we want to show how one actually arrives at large eigenvalue problems in practice. In the following, we restrict ourselves to problems from physics [7, 18, 14] and computer science.

1.1 What makes eigenvalues interesting?

In physics, eigenvalues are usually related to vibrations. Objects like violin strings, drums, bridges, sky scrapers can swing. They do this at certain frequencies. And in some situations they swing so much that they are destroyed. On November 7, 1940, the Tacoma narrows bridge collapsed, less than half a year after its opening. Strong winds excited the bridge so much that the platform in reinforced concrete fell into pieces. A few years ago the London millennium footbridge started wobbling in a way that it had to be closed. The wobbling had been excited by the pedestrians passing the bridge. These are prominent examples of vibrating structures.

But eigenvalues appear in many other places. Electric fields in cyclotrones, a special form of particle accelerators, have to oscillate in a precise manner, in order to accelerate the charged particles that circle around its center. The solutions of the Schrödinger equation from quantum physics and quantum chemistry have solutions that correspond to vibrations of the, say, molecule it models. The eigenvalues correspond to energy levels that molecule can occupy.

Many characteristic quantities in science are eigenvalues:

- decay factors,
- frequencies,
- norms of operators (or matrices),
- singular values,
- condition numbers.

In the sequel we give a number of examples that show why computing eigenvalues is important. At the same time we introduce some notation.
CHAPTER 1. INTRODUCTION

1.2 Example 1: The vibrating string

1.2.1 Problem setting

Let us consider a string as displayed in Fig. 1.1. The string is fixed at both ends, at \( x = 0 \) and \( x = L \). The \( x \)-axis coincides with the string’s equilibrium position. The displacement of the rest position at \( x, 0 < x < L \), and time \( t \) is denoted by \( u(x, t) \).

We will assume that the spatial derivatives of \( u \) are not very large:

\[
\left| \frac{\partial u}{\partial x} \right| \text{ is small.}
\]

This assumption entails that we may neglect terms of higher order.

Let \( v(x, t) \) be the velocity of the string at position \( x \) and at time \( t \). Then the kinetic energy of a string section \( ds \) of mass \( dm = \rho \, ds \) is given by

\[
(1.1) \quad dT = \frac{1}{2} dm \, v^2 = \frac{1}{2} \rho \, ds \left( \frac{\partial u}{\partial t} \right)^2.
\]

From Fig. 1.2 we see that \( ds^2 = dx^2 + \left( \frac{\partial u}{\partial x} \right)^2 \, dx^2 \) and thus

\[
\frac{ds}{dx} = \sqrt{1 + \left( \frac{\partial u}{\partial x} \right)^2} = 1 + \frac{1}{2} \left( \frac{\partial u}{\partial x} \right)^2 + \text{higher order terms.}
\]

Plugging this into (1.1) and omitting also the second order term (leaving just the number 1) gives

\[
dT = \frac{\rho}{2} dx \left( \frac{\partial u}{\partial t} \right)^2.
\]

The kinetic energy of the whole string is obtained by integrating over its length,

\[
T = \int_0^L dT(x) = \frac{1}{2} \int_0^L \rho(x) \left( \frac{\partial u}{\partial t} \right)^2 \, dx.
\]

The potential energy of the string has two components
1.2. EXAMPLE 1: THE VIBRATING STRING

Figure 1.2: A vibrating string, local picture.

1. the stretching times the exerted strain $\tau$,

$$
\tau \int_0^L ds - \tau \int_0^L dx = \tau \int_0^L \left( \sqrt{1 + \left( \frac{\partial u}{\partial x} \right)^2} - 1 \right) dx \\
= \tau \int_0^L \left( \frac{1}{2} \left( \frac{\partial u}{\partial x} \right)^2 + \text{higher order terms} \right) dx
$$

2. exterior forces of density $f$,

$$
- \int_0^L f u dx.
$$

Summing up, the potential energy of the string becomes

$$
V = \int_0^L \left( \frac{\tau}{2} \left( \frac{\partial u}{\partial x} \right)^2 - f u \right) dx.
$$

To consider the motion (vibration) of the string in a certain time interval $t_1 \leq t \leq t_2$ we form the integral

$$
I(u) = \int_{t_1}^{t_2} (T - V) dt = \frac{1}{2} \int_{t_1}^{t_2} \int_0^L \left[ \rho(x) \left( \frac{\partial u}{\partial t} \right)^2 - \tau \left( \frac{\partial u}{\partial x} \right)^2 + 2fu \right] dx dt
$$

Here functions $u(x,t)$ are admitted that are differentiable with respect to $x$ and $t$ and satisfy the boundary conditions (BC) that correspond to the fixing,

$$
u(0,t) = u(L,t) = 0, \quad t_1 \leq t \leq t_2,
$$

as well as given initial conditions and end conditions,

$$
u(x,t_1) = u_1(x), \quad u(x,t_2) = u_2(x), \quad 0 < x < L.
$$
CHAPTER 1. INTRODUCTION

According to the principle of Hamilton a mechanical system with kinetic energy $T$ and potential energy $V$ behaves in a time interval $t_1 \leq t \leq t_2$ for given initial and end positions such that

$$I = \int_{t_1}^{t_2} L \, dt, \quad L = T - V,$$

is minimized.

Let $u(x, t)$ be such that $I(u) \leq I(w)$ for all $w$, that satisfy the initial, end, and boundary conditions. Let $w = u + \varepsilon v$ with

\[(*) \quad v(0, t) = v(L, t) = 0, \quad v(x, t_1) = v(x, t_2) = 0.\]

$v$ is called a variation. We now consider $I(u + \varepsilon v)$ as a function of $\varepsilon$. Then we have the equivalence

$I(u)$ minimal $\iff \frac{dI}{d\varepsilon}(u) = 0$ for all admitted $v$.

Plugging $u + \varepsilon v$ into eq. (1.3) we obtain

\[
I(u + \varepsilon v) = \frac{1}{2} \int_{t_1}^{t_2} \int_0^L \left[ \rho(x) \left( \frac{\partial (u + \varepsilon v)}{\partial t} \right)^2 - \tau \left( \frac{\partial (u + \varepsilon v)}{\partial x} \right)^2 + 2f(u + \varepsilon v) \right] \, dx \, dt
\]

(1.6)

\[
= I(u) + \varepsilon \int_{t_1}^{t_2} \int_0^L \left[ \rho(x) \frac{\partial u}{\partial t} \frac{\partial v}{\partial t} - \tau \frac{\partial u}{\partial x} \frac{\partial v}{\partial x} + 2f v \right] \, dx \, dt + O(\varepsilon^2).
\]

Thus, after integration by parts, exploiting the conditions in (*), the equation

$$\frac{\partial I}{\partial \varepsilon} = \int_{t_1}^{t_2} \int_0^L \left[ \frac{\rho}{\partial t^2} - \tau \frac{\partial^2 u}{\partial x^2} + 2f \right] v \, dx \, dt = 0$$

must hold for all admissible $v$. Therefore, the bracketed expression must vanish,

(1.7)

$$-\rho \frac{\partial^2 u}{\partial t^2} + \tau \frac{\partial^2 u}{\partial x^2} = 2f.$$

This last differential equation is named Euler-Lagrange equation.

If the force is proportional to the displacement $u(x, t)$ (like, e.g., in Hooke’s law) then we get a differential equation of the form

(1.8)

\[
-\rho(x) \frac{\partial^2 u}{\partial t^2} + \frac{\partial}{\partial x} \left( p(x) \frac{\partial u}{\partial x} \right) + q(x) u(x, t) = 0.
\]

$u(0, t) = u(1, t) = 0$

which is a special case of the Euler-Lagrange equation (1.7). Here, $\rho(x)$ plays the role of a mass density, $p(x)$ of a locally varying elasticity module. We do not specify initial and end conditions for the moment. Note that there are no external forces present in (1.8).

From physics we know that $\rho(x) > 0$ and $p(x) > 0$ for all $x$. These properties are of importance also from a mathematical viewpoint! For simplicity, we assume that $\rho(x) = 1$. 
1.2. EXAMPLE 1: THE VIBRATING STRING

1.2.2 The method of separation of variables

For the solution \( u \) in (1.8) we make the ansatz

\[
(1.9) \quad u(x, t) = v(t)w(x).
\]

Here, \( v \) is a function that depends only on the time \( t \), while \( w \) depends only on the spatial variable \( x \). With this ansatz (1.8) becomes

\[
(1.10) \quad v''(t)w(x) - v(t)(p(x)w'(x))' - q(x)v(t)w(x) = 0.
\]

Now we separate the variables depending on \( t \) from those depending on \( x \),

\[
 \frac{v''(t)}{v(t)} = \frac{1}{w(x)}(p(x)w'(x))' + q(x).
\]

This equation holds for any \( t \) and \( x \). We can vary \( t \) and \( x \) independently of each other without changing the value on each side of the equation. Therefore, each side of the equation must be equal to a constant value. We denote this value by \(-\lambda\). Thus, from the left side we obtain the equation

\[
(1.11) \quad -v''(t) = \lambda v(t).
\]

This equation has the well-known solution \( v(t) = a \cdot \cos(\sqrt{\lambda}t) + b \cdot \sin(\sqrt{\lambda}t) \) where \( \lambda > 0 \) is assumed. The right side of (1.10) gives a so-called Sturm-Liouville problem

\[
(1.12) \quad -(p(x)w'(x))' + q(x)w(x) = \lambda w(x), \quad w(0) = w(1) = 0.
\]

A value \( \lambda \) for which (1.12) has a non-trivial (i.e. nonzero) solution \( w \) is called an eigenvalue; \( w \) is a corresponding eigenfunction. It is known that all eigenvalues of (1.12) are positive. By means of our ansatz (1.9) we get

\[
(1.13) \quad u(x, t) = \sum_{k=0}^{\infty} w_k(x) \left[ a_k \cdot \cos(\sqrt{\lambda_k} t) + b_k \cdot \sin(\sqrt{\lambda_k} t) \right].
\]

The coefficients \( a_k \) and \( b_k \) are determined by initial and end conditions. We could, e.g., require that

\[
 u(x, 0) = \sum_{k=0}^{\infty} a_k w_k(x) = u_0(x), \quad \frac{\partial u}{\partial t}(x, 0) = \sum_{k=0}^{\infty} \sqrt{\lambda_k} b_k w_k(x) = u_1(x),
\]

where \( u_0 \) and \( u_1 \) are given functions. It is known that the \( w_k \) form an orthogonal basis in the space of square integrable functions \( L_2(0, 1) \),

\[
 \int_0^1 w_k(x)w_\ell(x)dx = \gamma_k \delta_{k\ell}.
\]
Therefore, it is not difficult to compute the coefficients $a_k$ and $b_k$,

$$a_k = \int_0^1 u_0(x) w_k(x) \, dx / \gamma_k, \quad b_k = \int_0^1 u_1(x) w_k(x) \, dx / \gamma_k \sqrt{\lambda_k}.$$  

In concluding, we see that the difficult problem to solve is the eigenvalue problem (1.12). Knowing the eigenvalues and eigenfunctions the general solution of the time-dependent problem (1.8) is easy to form.

Eq. (1.12) can be solved analytically only in very special situation, e.g., if all coefficients are constants. In general a numerical method is needed to solve the Sturm-Liouville problem (1.12).

1.3 Numerical methods for solving 1-dimensional problems

In this section we consider three methods to solve the Sturm-Liouville problem.

1.3.1 Finite differences

We approximate $w(x)$ by its values at the discrete points $x_i = ih$, $h = 1/(n + 1)$, $i = 1, \ldots, n$.

![Figure 1.3: Grid points in the interval $(0, L)$.

At point $x_i$ we approximate the derivatives by finite differences. We proceed as follows. First we write

$$\frac{d}{dx} g(x_i) \approx \frac{g(x_{i+\frac{1}{2}}) - g(x_{i-\frac{1}{2}})}{h}.$$ 

For $g = p \frac{dw}{dx}$ we get

$$g(x_{i+\frac{1}{2}}) = p(x_{i+\frac{1}{2}}) \frac{w(x_{i+1}) - w(x_i)}{h}$$

and, finally, for $i = 1, \ldots, n$,

$$-\frac{d}{dx} \left( p \frac{dw}{dx} (x_i) \right) \approx -\frac{1}{h} \left[ p(x_{i+\frac{1}{2}}) \frac{w(x_{i+1}) - w(x_i)}{h} - p(x_{i-\frac{1}{2}}) \frac{w(x_i) - w(x_{i-1})}{h} \right]$$

$$= \frac{1}{h^2} \left[ -p(x_{i-\frac{1}{2}}) w_{i-1} + (p(x_{i-\frac{1}{2}}) + p(x_{i+\frac{1}{2}})) w_i - p(x_{i+\frac{1}{2}}) w_{i+1} \right].$$

Note that at the interval endpoints $w_0 = w_{n+1} = 0$.

We can collect all equations in a matrix equation,

$$\begin{bmatrix}
\frac{p(x_{\frac{1}{2}})}{h^2} & -\frac{p(x_{\frac{1}{2}})}{h^2} & \frac{p(x_{\frac{1}{2}})}{h^2} & \cdots & \frac{p(x_{\frac{1}{2}})}{h^2} \\
-\frac{p(x_{\frac{3}{2}})}{h^2} & \frac{p(x_{\frac{3}{2}})}{h^2} & -\frac{p(x_{\frac{3}{2}})}{h^2} & \cdots & \frac{p(x_{\frac{3}{2}})}{h^2} \\
\frac{p(x_{\frac{5}{2}})}{h^2} & -\frac{p(x_{\frac{5}{2}})}{h^2} & \frac{p(x_{\frac{5}{2}})}{h^2} & \cdots & \frac{p(x_{\frac{5}{2}})}{h^2} \\
\cdots & \cdots & \cdots & \cdots & \cdots \\
\end{bmatrix} \begin{bmatrix}
w_1 \\
w_2 \\
w_3 \\
\vdots \\
w_n
\end{bmatrix} = \lambda \begin{bmatrix}
w_1 \\
w_2 \\
w_3 \\
\vdots \\
w_n
\end{bmatrix},$$
1.3. NUMERICAL METHODS FOR SOLVING 1-DIMENSIONAL PROBLEMS

or, briefly,

\[(1.14) \quad A w = \lambda w.\]

By construction, $A$ is symmetric and tridiagonal. One can show that it is positive definite as well. Note that this matrix has just a few nonzeros: out of the $n^2$ elements of $A$ only $3n - 2$ are nonzero. This is an example of a \textbf{sparse} matrix.

1.3.2 The finite element method

We write (1.12) in the form

Find a twice differentiable function $w$ with $w(0) = w(1) = 0$ such that

\[
\int_0^1 \left[ -(p(x)w'(x))' + q(x)w(x) - \lambda w(x) \right] \phi(x) dx = 0
\]

for all smooth functions $\phi$ that satisfy $\phi(0) = \phi(1) = 0$.

To relax the requirements on $w$ we integrate by parts and get the new so-called \textit{weak} or \textit{variational form} of the problem:

Find a differentiable function $w$ with $w(0) = w(1) = 0$ such that

\[(1.15) \quad \int_0^1 \left[ p(x)w(x)'\phi'(x) + q(x)w(x)\phi(x) - \lambda w(x)\phi(x) \right] dx = 0\]

for all differentiable functions $\phi$ that satisfy $\phi(0) = \phi(1) = 0$.

\noindent \textbf{Remark:} Requiring continuous differentiability is too strong and does not lead to a mathematically suitable formulation. In particular, the test functions that will be used below are not differentiable in the classical sense. It is more appropriate to require $w$ and $\phi$ to be \textit{weakly} differentiable. In terms of Sobolev spaces: $w, \phi \in H^1_0([0,1])$. An introduction to Sobolev spaces is, however, beyond the scope of these notes.

\node at (4.5,0) {$L$};
\end{tikzpicture}
\caption{A basis function of the finite element space: a hat function.}
\end{figure}

We now write $w$ as the linear combination

\[(1.16) \quad w(x) = \sum_{i=1}^n \xi_i \Psi_i(x),\]

where

\[(1.17) \quad \Psi_i(x) = \left( 1 - \frac{|x - x_i|}{h} \right)_+ = \max\{0, 1 - \frac{|x - x_i|}{h}\},\]
is the function that is linear in each interval \((x_i, x_{i+1})\) and satisfies
\[
\Psi_i(x_k) = \delta_{ik} := \begin{cases} 
1, & i = k, \\
0, & i \neq k.
\end{cases}
\]

An example of such a basis function, a so-called hat function, is displayed in Fig. 1.4.

We now replace \(w\) in (1.15) by the linear combination (1.16), and replace testing ‘against all \(\phi\’ by testing against all \(\Psi_j\). In this way (1.15) becomes
\[
\int_0^1 \left( -p(x) \left( \sum_{i=1}^n \xi_i \Psi'_i(x) \right) \Psi'_j(x) + (q(x) - \lambda) \sum_{i=1}^n \xi_i \Psi_i(x) \Psi_j(x) \right) dx, \quad \text{for all } j,
\]
or,
\[
\sum_{i=1}^n \xi_i \int_0^1 \left( p(x) \Psi'_i(x) \Psi'_j(x) + (q(x) - \lambda) \Psi_i(x) \Psi_j(x) \right) dx = 0, \quad \text{for all } j.
\]
These last equations are called the Rayleigh–Ritz–Galerkin equations. Unknown are the \(n\) values \(\xi_i\) and the eigenvalue \(\lambda\). In matrix notation (1.18) becomes
\[
A \mathbf{x} = \lambda M \mathbf{x}
\]
with
\[
a_{ij} = \int_0^1 \left( p(x) \Psi'_i(x) \Psi'_j(x) + q(x) \Psi_i(x) \Psi_j(x) \right) dx \quad \text{and} \quad m_{ij} = \int_0^1 \Psi_i(x) \Psi_j(x) dx
\]

For the specific case \(p(x) = 1 + x\) and \(q(x) = 1\) we get
\[
a_{kk} = \int_{(k-1)h}^{kh} \left( 1 + x \right) \frac{1}{h^2} + \left( \frac{x - (k-1)h}{h} \right)^2 \ dx
+ \int_{kh}^{(k+1)h} \left( 1 + x \right) \frac{1}{h^2} + \left( \frac{(k+1)h - x}{h} \right)^2 \ dx = 2(n+1+k) + \frac{2}{3} \frac{1}{n+1}
\]
\[
a_{k,k+1} = \int_{kh}^{(k+1)h} \left( 1 + x \right) \frac{1}{h^2} + \frac{(k+1)h - x}{h} \cdot \frac{x - kh}{h} \ dx = -n - \frac{3}{2} - k + \frac{1}{6n+1}
\]

In the same way we get
\[
M = \frac{1}{6(n+1)} \begin{bmatrix} 4 & 1 \\ 1 & 4 & \ddots \\ \vdots & \ddots & \ddots & 1 \\ 1 & 4 \end{bmatrix}
\]

Notice that both matrices \(A\) and \(M\) are symmetric tridiagonal and positive definite.

### 1.3.3 Global functions

Formally we proceed as with the finite element method, i.e., we solve equation (1.18). But now we choose the \(\Psi_k(x)\) to be functions with global support\(^1\). We could, e.g., set
\[
\Psi_k(x) = \sin k \pi x,
\]
\(^1\)The support of a function \(f\) is the set of arguments \(x\) for which \(f(x) \neq 0\).
functions that are differentiable and satisfy the homogeneous boundary conditions. The $\Psi_k$ are eigenfunctions of the nearby problem $-u''(x) = \lambda u(x)$, $u(0) = u(1) = 0$ corresponding to the eigenvalue $k^2\pi^2$. The elements of matrix $A$ are given by

$$a_{kk} = \int_0^1 [(1 + x)k^2\pi^2 \cos^2 k\pi x + \sin^2 k\pi x] \, dx = \frac{3}{4} k^2\pi^2 + \frac{1}{2},$$

$$a_{kj} = \int_0^1 [(1 + x)kj\pi^2 \cos k\pi x \cos j\pi x + \sin k\pi x \sin j\pi x] \, dx = \frac{2kj(k^2 + j^2)((-1)^{k+j} - 1)}{(k^2 - j^2)^2}, \quad k \neq j.$$

### 1.3.4 A numerical comparison

We consider the above 1-dimensional eigenvalue problem

$$(1.20) \quad -((1 + x)w'(x))' + w(x) = \lambda w(x), \quad w(0) = w(1) = 0,$$

and solve it with the finite difference and finite element methods as well as with the global functions method. The results are given in Table 1.1.

Clearly the global function method is the most powerful of them all. With 80 basis functions the eigenvalues all come right. The convergence rate is exponential.

With the finite difference and finite element methods the eigenvalues exhibit quadratic convergence rates. If the mesh width $h$ is reduced by a factor of $q = 2$, the error in the eigenvalues is reduced by the factor $q^2 = 4$. There exist higher order finite elements and higher order finite difference stencils [11, 6].

### 1.4 Example 2: The heat equation

The instationary temperature distribution $u(x,t)$ in an insulated container satisfies the equations

$$(1.21) \quad \frac{\partial u(x,t)}{\partial t} - \Delta u(x,t) = 0, \quad x \in \Omega, \quad t > 0,$$

$$\frac{\partial u(x,t)}{\partial n} = 0, \quad x \in \partial\Omega, \quad t > 0,$$

$$u(x,0) = u_0(x), \quad x \in \Omega.$$

Here $\Omega$ is a 3-dimensional domain$^2$ with boundary $\partial\Omega$. $u_0(x), x = (x_1, x_2, x_3)^T \in \mathbb{R}^3$, is a given bounded, sufficiently smooth function.

$$(1.22) \quad \Delta u = \sum \frac{\partial^2 u}{\partial x_i^2}$$

is called the **Laplace operator** and $\frac{\partial u}{\partial n}$ denotes the derivative of $u$ in direction of the outer normal vector $\mathbf{n}$. To solve the heat equation the **method of separation of variables** is employed. We write $u$ in the form

$$(1.23) \quad u(x,t) = v(t)w(x).$$

$^2$In the sequel we understand a domain to be bounded and simply connected.

Table 1.1: Numerical solutions of problem (1.20)
If a constant \( \lambda \) can be found such that

\[
\Delta w(x) + \lambda w(x) = 0, \quad w(x) \neq 0, \quad x \text{ in } \Omega,
\]

\[
\frac{\partial w(x)}{\partial n} = 0, \quad x \text{ on } \partial \Omega,
\]

then the product \( u = vw \) is a solution of (1.21) if and only if

\[
\frac{dv(t)}{dt} + \lambda v(t) = 0,
\]

the solution of which has the form \( a \exp(-\lambda t) \). By separating variables, the problem (1.21) is divided into two subproblems that are hopefully easier to solve. A value \( \lambda \), for which (1.24) has a nontrivial (i.e., a nonzero) solution is called an eigenvalue; \( w \) then is called a corresponding eigenfunction.

If \( \lambda_n \) is an eigenvalue of problem (1.24) with corresponding eigenfunction \( w_n \), then

\[
e^{-\lambda_n t}w_n(x)
\]

is a solution of the first two equations in (1.21). It is known that equation (1.24) has infinitely many real eigenvalues \( 0 \leq \lambda_1 \leq \lambda_2 \leq \cdots \), that tend to infinity, \( \lambda_n \to \infty \) as \( n \to \infty \). Multiple eigenvalues are counted according to their multiplicity. An arbitrary bounded piecewise continuous function can be represented as a linear combination of the eigenfunctions \( w_1, w_2, \ldots \). Therefore, the solution of (1.21) can be written in the form

\[
(1.26) \quad u(x, t) = \sum_{n=1}^{\infty} c_n e^{-\lambda_n t}w_n(x),
\]

where the coefficients \( c_n \) are determined such that

\[
(1.27) \quad u_0(x) = \sum_{n=1}^{\infty} c_n w_n(x).
\]

The smallest eigenvalue of (1.24) is \( \lambda_1 = 0 \) with \( w_1 = 1 \) and \( \lambda_2 > 0 \). Therefore we see from (1.26) that

\[
(1.28) \quad u(x, t) \underset{t \to \infty}{\to} c_1.
\]

Thus, in the limit (i.e., as \( t \) goes to infinity), the temperature will be constant in the whole container. The convergence rate towards this equilibrium is determined by the smallest positive eigenvalue \( \lambda_2 \) of (1.24):

\[
\|u(x, t) - c_1\| = \left\| \sum_{n=2}^{\infty} c_n e^{-\lambda_n t}w_n(x) \right\| \leq \sum_{n=2}^{\infty} |e^{-\lambda_n t}|\|c_n w_n(x)\| \\
\leq e^{-\lambda_2 t} \sum_{n=2}^{\infty} \|c_n w_n(x)\| \leq e^{-\lambda_2 t}\|u_0(x)\|.
\]

Here we have assumed that the value of the constant function \( w_1(x) \) is set to unity.
CHAPTER 1. INTRODUCTION

1.5 Example 3: The wave equation

The air pressure \( u(x, t) \) in a volume with acoustically “hard” walls satisfies the equations

\[
\frac{\partial^2 u(x, t)}{\partial t^2} - \Delta u(x, t) = 0, \quad x \in \Omega, \ t > 0, \tag{1.29}
\]

\[
\frac{\partial u(x, t)}{\partial n} = 0, \quad x \in \partial \Omega, \ t > 0, \tag{1.30}
\]

\[
u(x, 0) = u_0(x), \quad x \in \Omega, \tag{1.31}
\]

\[
\frac{\partial u(x, 0)}{\partial t} = u_1(x), \quad x \in \Omega. \tag{1.32}
\]

Sound propagates with speed \(-\nabla u\), along the (negative) gradient from high to low pressure.

To solve the wave equation we proceed as with the heat equation in section 1.4: separation of \( u \) according to (1.23) leads again to equation (1.24) but now together with

\[
\frac{d^2 v(t)}{dt^2} + \lambda v(t) = 0. \tag{1.33}
\]

We know this equation from the analysis of the vibrating string, see (1.11). From there we know that the general solution of the wave equation has the form

\[
u(x, t) = \sum_{k=0}^{\infty} w(x) \left[ A_k \cdot \cos(\sqrt{\lambda_k} t) + B_k \cdot \sin(\sqrt{\lambda_k} t) \right], \tag{1.13}
\]

where the \( w_k, k = 1, 2, \ldots \), are the eigenfunctions of the eigenvalue problem (1.24). The coefficients \( a_k \) and \( b_k \) are determined by (1.31) and (1.32).

If a harmonic oscillation is forced on the system, an inhomogeneous problem

\[
\frac{\partial^2 u(x, t)}{\partial t^2} - \Delta u(x, t) = f(x, t), \tag{1.34}
\]

is obtained. The boundary and initial conditions are taken from (1.29)–(1.32). This problem can be solved by expanding \( u \) and \( f \) in the eigenfunctions \( w_n(x) \),

\[
u(x, t) := \sum_{n=1}^{\infty} \tilde{v}_n(t) w_n(x),
\]

\[
f(x, t) := \sum_{n=1}^{\infty} \phi_n(t) w_n(x). \tag{1.35}
\]

With this approach, \( \tilde{v}_n \) has to satisfy equation

\[
\frac{d^2 \tilde{v}_n}{dt^2} + \lambda_n \tilde{v}_n = \phi_n(t). \tag{1.36}
\]

If \( \phi_n(t) = a_n \sin \omega t \), then the solution becomes

\[
\tilde{v}_n = A_n \cos \sqrt{\lambda_n} t + B_n \sin \sqrt{\lambda_n} t + \frac{1}{\lambda_n - \omega^2} a_n \sin \omega t. \tag{1.37}
\]
$A_n$ and $B_n$ are real constants that are determined by the initial conditions. If $\omega$ gets close to $\sqrt{\lambda_n}$, then the last term can be very large. In the limit, if $\omega = \sqrt{\lambda_n}$, $\tilde{v}_n$ gets the form

$$\tilde{v}_n = A_n \cos \sqrt{\lambda_n} t + B_n \sin \sqrt{\lambda_n} t + a_n t \sin \omega t,$$

in which case, $\tilde{v}_n$ is not bounded in time anymore. This phenomenon is called resonance. Often resonance is not desirable; it may, e.g., mean the blow up of some structure. In order to prevent resonances eigenvalues have to be known. Possible remedies are changing the domain (the structure) or parameters (the materials).

Remark 1.1. Vibrating membranes satisfy the wave equation, too. In general the boundary conditions are different from (1.30). If the membrane (of a drum) is fixed at its boundary, the condition

$$u(x,t) = 0$$

is imposed. These boundary conditions are called Dirichlet boundary conditions. The boundary conditions in (1.21) and (1.30) are called Neumann boundary conditions. Combinations of these two can occur.

1.6 Numerical methods for solving the Laplace eigenvalue problem in 2D

In this section we again consider the eigenvalue problem

$$(1.40) \quad -\Delta u(x) = \lambda u(x), \quad x \in \Omega,$$

with the more general boundary conditions

$$u(x) = 0, \quad x \in \Gamma_1 \subset \partial \Omega,$$

$$\frac{\partial u}{\partial n}(x) + \alpha(x) u(x) = 0, \quad x \in \Gamma_2 \subset \partial \Omega.$$ 

Here, $\Gamma_1$ and $\Gamma_2$ are disjoint subsets of $\partial \Omega$ with $\Gamma_1 \cup \Gamma_2 = \partial \Omega$. We restrict ourselves in the following on two-dimensional domains and write $(x,y)$ instead of $(x_1, x_2)$.

In general it is not possible to solve a problem of the form (1.40)–(1.42) exactly (analytically). Therefore, one has to resort to numerical approximations. Because we cannot compute with infinitely many variables we have to construct a finite-dimensional eigenvalue problem that represents the given problem as well as possible, i.e., that yields good approximations for the desired eigenvalues and eigenvectors. Since finite-dimensional eigenvalue problem only have a finite number of eigenvalues one cannot expect to get good approximations for all eigenvalues of (1.40)–(1.42).

Two methods for the discretization of eigenvalue problems of the form (1.40)–(1.42) are the Finite Difference Method [11, 16, 9] and the Finite Element Method (FEM) [6, 15, 8]. We briefly introduce these methods in the following subsections.

1.6.1 The finite difference method

In this section we just want to mediate some impression what the finite difference method is about. Therefore we assume for simplicity that the domain $\Omega$ is a square with sides of
CHAPTER 1. INTRODUCTION

length 1: \( \Omega = (0, 1) \times (0, 1) \). We consider the eigenvalue problem

\[
-\Delta u(x, y) = \lambda u(x, y), \quad 0 < x, y < 1 \\
u(0, y) = u(1, y) = u(x, 0) = 0, \quad 0 < x, y < 1, \\
\frac{\partial u}{\partial n}(x, 1) = 0, \quad 0 < x < 1.
\]

This eigenvalue problem occurs in the computation of eigenfrequencies and eigenmodes of a homogeneous quadratic membrane with three fixed and one free side. It can be solved analytically by separation of the two spatial variables \( x \) and \( y \). The eigenvalues are

\[ \lambda_{k,l} = \left( k^2 + \frac{(2l - 1)^2}{4} \right) \pi^2, \quad k, l \in \mathbb{N}, \]

and the corresponding eigenfunctions are

\[ u_{k,l}(x, y) = \sin k\pi x \sin \frac{2l - 1}{2} \pi y. \]

In the finite difference method one proceeds by defining a rectangular grid with grid points \((x_i, y_j), 0 \leq i, j \leq N\). The coordinates of the grid points are

\[ (x_i, y_j) = (ih, jh), \quad h = 1/N. \]

By a Taylor expansion one can show that for sufficiently smooth functions \( u \)

\[
-\Delta u(x, y) = \frac{1}{h^2} (4u(x, y) - u(x - h, y) - u(x + h, y) - u(x, y - h) - u(x, y + h)) + O(h^2).
\]

It is therefore straightforward to replace the differential equation \(-\Delta u(x, y) = \lambda u(x, y)\) by a difference equation at the interior grid points

\[
4u_{i,j} - u_{i-1,j} - u_{i+1,j} - u_{i,j-1} - u_{i,j+1} = \lambda h^2 u_{i,j}, \quad 0 < i, j < N.
\]

We consider the unknown variables \( u_{i,j} \) as approximations of the eigenfunctions at the grid points \((i, j)\):

\[
u_{i,j} \approx u(x_i, x_j).
\]

The Dirichlet boundary conditions are replaced by the equations

\[
u_{i,0} = u_{i,N} = u_{0,i}, \quad 0 < i < N.
\]

At the points at the upper boundary of \( \Omega \) we first take the difference equation (1.44)

\[
4u_{i,N} - u_{i-1,N} - u_{i+1,N} - u_{i,N-1} - u_{i,N+1} = \lambda h^2 u_{i,N}, \quad 0 \leq i \leq N.
\]

The value \( u_{i,N+1} \) corresponds to a grid point outside of the domain! However the Neumann boundary conditions suggest to reflect the domain at the upper boundary and to extend the eigenfunction symmetrically beyond the boundary. This procedure leads to the equation \( u_{i,N+1} = u_{i,N-1} \). Plugging this into (1.47) and multiplying the new equation by the factor \( 1/2 \) gives

\[
2u_{i,N} - \frac{1}{2} u_{i-1,N} - \frac{1}{2} u_{i+1,N} - u_{i,N-1} = \frac{1}{2} \lambda h^2 u_{i,N}, \quad 0 < i < N.
\]
In summary, from (1.44) and (1.48), taking into account that (1.46) we get the matrix equation

\[
\begin{pmatrix}
4 & -1 & 0 & -1 \\
-1 & 4 & -1 & 0 & -1 \\
0 & -1 & 4 & 0 & 0 & -1 \\
-1 & 0 & 0 & 4 & 0 & 0 & -1 \\
-1 & 0 & -1 & 4 & 0 & 0 & -1 \\
-1 & 0 & -1 & 4 & -1 & 0 & -1 \\
-1 & 0 & -1 & 4 & 0 & 0 & -1 \\
-1 & 0 & 0 & 2 & -\frac{1}{2} & 0 & \frac{1}{2} \\
-1 & 0 & -\frac{1}{2} & 2 & -\frac{1}{2} & 0 & \frac{1}{2} \\
-1 & 0 & -\frac{1}{2} & 2 & -\frac{1}{2} & 0 & \frac{1}{2}
\end{pmatrix}
\begin{pmatrix}
u_{1,1} \\
u_{1,2} \\
u_{1,3} \\
u_{2,1} \\
u_{2,2} \\
u_{2,3} \\
u_{3,1} \\
u_{3,2} \\
u_{3,3} \\
u_{4,1} \\
u_{4,2} \\
u_{4,3}
\end{pmatrix}
= \lambda h^2
\begin{pmatrix}
1 \\
1 \\
1 \\
1 \\
1 \\
1
\end{pmatrix}
\begin{pmatrix}
u_{1,1} \\
u_{1,2} \\
u_{1,3} \\
u_{2,1} \\
u_{2,2} \\
u_{2,3} \\
u_{3,1} \\
u_{3,2} \\
u_{3,3} \\
u_{4,1} \\
u_{4,2} \\
u_{4,3}
\end{pmatrix}
\]

For arbitrary \( N > 1 \) we define

\[
u_i := \begin{pmatrix}
u_{i,1} \\
u_{i,2} \\
\vdots \\
u_{i,N-1}
\end{pmatrix} \in \mathbb{R}^{N-1},
\]

\[
T := \begin{pmatrix}
4 & -1 & & & & \\
-1 & 4 & & & & \\
& & \ddots & & & \\
& & & \ddots & & \\
& & & & -1 & -1 \\
& & & & & 4
\end{pmatrix} \in \mathbb{R}^{(N-1) \times (N-1)},
\]

\[
I := \begin{pmatrix}
1 & & & & \cdot \\
1 & & & & \cdot \\
& & & & \cdot \\
& & & & \cdot \\
& & & & \cdot \\
1
\end{pmatrix} \in \mathbb{R}^{(N-1) \times (N-1)}.
\]
In this way we obtain from (1.44), (1.46), (1.48) the discrete eigenvalue problem

\begin{equation}
\begin{bmatrix}
T & -I \\
-I & T & \ddots \\
& \ddots & \ddots & -I \\
& & \ddots & -I \\
& & & \frac{1}{4}I
\end{bmatrix}
\begin{bmatrix}
u_1 \\
\vdots \\
u_3 \\
u_4
\end{bmatrix}
= \lambda h^2
\begin{bmatrix}
I \\
\vdots \\
I \\
\frac{1}{2}I
\end{bmatrix}
\begin{bmatrix}
u_1 \\
\vdots \\
u_{N-1} \\
u_N
\end{bmatrix}
\end{equation}

of size \(N \times (N - 1)\). This is a **matrix eigenvalue problem** of the form

\begin{equation}
Ax = \lambda Mx,
\end{equation}

where \(A\) and \(M\) are **symmetric** and \(M\) additionally is **positive definite**. If \(M\) is the identity matrix, we call (1.51) a **special** and otherwise a **generalized** eigenvalue problem. In these lecture notes we deal with numerical methods, to solve eigenvalue problems like these.

In the case (1.50) it is easy to obtain a special (symmetric) eigenvalue problem by a simple transformation: By left multiplication by

\begin{equation}
\begin{bmatrix}
I & & \\
& I & \\
& & \sqrt{2}I
\end{bmatrix}
\end{equation}

we obtain from (1.50)

\begin{equation}
\begin{bmatrix}
T & -I \\
-I & T & -I \\
& \ddots & \ddots & -I \\
& & \ddots & -I \\
& & & \frac{1}{4}I
\end{bmatrix}
\begin{bmatrix}
u_1 \\
\vdots \\
u_3 \\
u_4
\end{bmatrix}
= \lambda h^2
\begin{bmatrix}
u_1 \\
\vdots \\
u_{N-1} \\
\sqrt{2}u_4
\end{bmatrix}.
\end{equation}

A property common to matrices obtained by the finite difference method are its **sparsity**. Sparse matrices have only very few nonzero elements.

In real-world applications domains often cannot be covered easily by a rectangular grid. In this situation and if boundary conditions are complicated the method of finite differences can be difficult to implement. Because of this the finite element method is often the method of choice.

Nevertheless, problems that are posed on rectangular grids can be solved very efficiently. Therefore, tricks are used to deal with irregular boundaries. The solution of the problem may be extended artificially beyond the boundary, see e.g. [1, 17, 9]. Similar techniques, so-called *impressed boundary conditions* are applied at (irregular) interfaces where, e.g., equations or parameters change [11].

#### 1.6.2 The finite element method (FEM)

Let \((\lambda, u) \in \mathbb{R} \times V\) be an eigenpair of problem (1.40)–(1.42). Then

\begin{equation}
\int_{\Omega} (\Delta u + \lambda u)v\,dx\,dy = 0, \quad \forall v \in V,
\end{equation}

where \(V\) is vector space of bounded twice differentiable functions that satisfy the boundary conditions (1.41)–(1.42). By partial integration (Green’s formula) this becomes

\begin{equation}
\int_{\Omega} \nabla u \nabla v\,dx\,dy + \int_{\Gamma_2} \alpha u v\,ds = \lambda \int_{\Omega} u v\,dx\,dy, \quad \forall v \in V,
\end{equation}
or

$$a(u, v) = (u, v), \quad \forall v \in V$$

where

$$a(u, v) = \int_{\Omega} \nabla u \nabla v \, dx \, dy + \int_{\Gamma_2} \alpha u v \, ds, \quad \text{and} \quad (u, v) = \int_{\Omega} u v \, dx \, dy.$$ 

We complete the space $V$ with respect to the Sobolev norm $[8, 3]$

$$\sqrt{\int_{\Omega} (u^2 + |\nabla u|^2) \, dx \, dy}$$

to become a Hilbert space $H$ [3, 19]. $H$ is the space of quadratic integrable functions with quadratic integrable first derivatives that satisfy the Dirichlet boundary conditions (1.41)

$$u(x, y) = 0, \quad (x, y) \in \Gamma_1.$$ 

(Functions in $H$ in general do not satisfy the so-called natural boundary conditions (1.42).) One can show [19] that the eigenvalue problem (1.40)–(1.42) is equivalent with the eigenvalue problem

$$a(u, v) = \lambda (u, v) \quad \forall v \in H.$$ 

(The essential point is to show that the eigenfunctions of (1.56) are elements of $V$.)

The Rayleigh–Ritz–Galerkin method

In the Rayleigh–Ritz–Galerkin method one proceeds as follows: A set of linearly independent functions

$$\phi_1(x, y), \ldots, \phi_n(x, y) \in H,$$

are chosen. These functions span a subspace $S$ of $H$. Then, problem (1.56) is solved where $H$ is replaced by $S$.

$$\text{Find } (\lambda, u) \in \mathbb{R} \times S \text{ such that } a(u, v) = \lambda (u, v) \quad \forall v \in S.$$ 

With the Ritz ansatz [15]

$$u = \sum_{i=1}^{n} x_i \phi_i,$$

equation (1.58) becomes

$$\text{Find } (\lambda, x) \in \mathbb{R} \times \mathbb{R}^n \text{ such that } \sum_{i=1}^{n} x_i a(\phi_i, v) = \lambda \sum_{i=1}^{n} x_i (\phi_i, v), \quad \forall v \in S.$$
CHAPTER 1. INTRODUCTION

Eq. (1.60) must hold for all \( v \in S \), in particular for \( v = \phi_1, \ldots, \phi_n \). But since the \( \phi_i, 1 \leq i \leq n \), form a basis of \( S \), equation (1.60) is equivalent with

\[
(1.61) \quad \sum_{i=1}^{n} x_i a(\phi_i, \phi_j) = \lambda \sum_{i=1}^{n} x_i (\phi_i, \phi_j), \quad 1 \leq j \leq n.
\]

This is a matrix eigenvalue problem of the form

\[
(1.62) \quad Ax = \lambda Mx
\]

where

\[
(1.63) \quad x = \begin{pmatrix} x_1 \\ \vdots \\ x_n \end{pmatrix}, \quad A = \begin{pmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & \ddots & \vdots \\ a_{n1} & \cdots & a_{nn} \end{pmatrix}, \quad M = \begin{pmatrix} m_{11} & \cdots & m_{1n} \\ \vdots & \ddots & \vdots \\ m_{n1} & \cdots & m_{nn} \end{pmatrix}
\]

with

\[
a_{ij} = a(\phi_i, \phi_j) = \int_{\Omega} \nabla \phi_i \nabla \phi_j \, dx \, dy + \int_{\Gamma_2} \alpha \phi_i \phi_j \, ds
\]

and

\[
m_{ij} = (\phi_i, \phi_j) = \int_{\Omega} \phi_i \phi_j \, dx \, dy.
\]

The finite element method (FEM) is a special case of the Rayleigh–Ritz method. In the FEM the subspace \( S \) and in particular the basis \( \{ \phi_i \} \) is chosen in a particularly clever way. For simplicity we assume that the domain \( \Omega \) is a simply connected domain with a polygonal boundary, c.f. Fig 1.5. (This means that the boundary is composed entirely of straight line segments.) This domain is now partitioned into triangular subdomains \( T_1, \ldots, T_N \), so-called elements, such that

\[
(1.64) \quad T_i \cap T_j = \emptyset \quad \text{for all } i \neq j, \quad \text{and} \quad \bigcup_{e} T_e = \overline{\Omega}.
\]

Finite element spaces for solving (1.40)–(1.42) are typically composed of functions that are continuous in \( \Omega \) and are polynomials on the individual subdomains \( T_e \). Such functions
are called \textit{piecewise polynomials}. Notice that this construction provides a subspace of the Hilbert space $H$ but not of $V$, i.e., the functions in the finite element space are not very smooth and the natural boundary conditions are not satisfied.

An essential issue is the selection of the \textit{basis} of the finite element space $S$. If $S_1 \subset H$ is the space of continuous, piecewise linear functions (the restriction to $T_e$ is a polynomial of degree 1) then a function in $S_1$ is uniquely determined by its values at the vertices of the triangles. Let these \textit{nodes}, except those on the boundary portion $\Gamma_1$, be numbered from 1 to $n$, see Fig. 1.6. Let the coordinates of the $i$-th node be $(x_i, y_i)$. Then $\phi_i(x, y) \in S_1$ is defined by

\[
\phi_i((x_j, y_j)) := \delta_{ij} = \begin{cases} 
1 & i = j \\
0 & i \neq j 
\end{cases}
\]

A typical basis function $\phi_i$ is sketched in Figure 1.7.

Another often used finite element element space is $S_2 \subset H$, the space of continuous, \textit{piecewise quadratic} polynomials. These functions are (or can be) uniquely determined by their values at the vertices and edge midpoints of the triangle. The basis functions are defined according to (1.65). There are two kinds of basis functions $\phi_i$ now, first those that are 1 at a vertex and second those that are 1 at an edge midpoint, cf. Fig. 1.8. One immediately sees that for most $i \neq j$

\[
a(\phi_i, \phi_j) = 0, \quad (\phi_i, \phi_j) = 0.
\]
Therefore the matrices $A$ and $M$ in (1.62)–(1.63) will be sparse. The matrix $M$ is positive definite as

\[
\mathbf{x}^T M \mathbf{x} = \sum_{i,j=1}^{N} x_i x_j m_{ij} = \sum_{i,j=1}^{N} x_i x_j (\phi_i, \phi_j) = (u, u) > 0, \quad u = \sum_{i=1}^{N} x_i \phi_i \neq 0,
\]

because the $\phi_i$ are linearly independent and because $||u|| = \sqrt{(u, u)}$ is a norm. Similarly it is shown that

\[
\mathbf{x}^T A \mathbf{x} \geq 0.
\]

It is possible to have $\mathbf{x}^T A \mathbf{x} = 0$ for a nonzero vector $\mathbf{x}$. This is the case if the constant function $u = 1$ is contained in $S$. This happens if Neumann boundary conditions $\frac{\partial u}{\partial n} = 0$ are posed on the whole boundary $\partial \Omega$. Then,

\[
u(x, y) = 1 = \sum_{i} \phi_i(x, y),
\]

i.e., we have $\mathbf{x}^T A \mathbf{x} = 0$ for $\mathbf{x} = [1, 1, \ldots, 1]$.

### 1.6.3 A numerical example

We want to determine the acoustic eigenfrequencies and corresponding modes in the interior of a car. This is of interest in the manufacturing of cars, since an appropriate shape of the form of the interior can suppress the often unpleasant droning of the motor. The problem is three-dimensional, but by separation of variables the problem can be reduced to two dimensions. If rigid, acoustically hard walls are assumed, the mathematical model of the problem is again the Laplace eigenvalue problem (1.24) together with Neumann boundary conditions. The domain is given in Fig. 1.9 where three finite element triangulations are shown with 87 (grid$_1$), 298 (grid$_2$), and 1095 (grid$_3$) vertices (nodes), respectively. The results obtained with piecewise linear polynomials are listed in Table 1.2. From the results we notice the quadratic convergence rate. The smallest eigenvalue is always zero. The corresponding eigenfunction is the constant function. This function can be represented exactly by the finite element spaces, whence its value is correct (up to rounding error).

The fourth eigenfunction of the acoustic vibration problem is displayed in Fig. 1.10. The physical meaning of the function value is the difference of the pressure at a given location to the normal pressure. Large amplitudes thus means that the corresponding noise is very much noticable.
1.7. CAVITY RESONANCES IN PARTICLE ACCELERATORS

The Maxwell equations in vacuum are given by

\[
\text{curl } \mathbf{E}(x, t) = -\frac{\partial \mathbf{B}}{\partial t}(x, t), \\
\text{curl } \mathbf{H}(x, t) = \frac{\partial \mathbf{D}}{\partial t}(x, t) + \mathbf{j}(x, t), \\
\text{div } \mathbf{D}(x, t) = \rho(x, t), \\
\text{div } \mathbf{B}(x, t) = 0.
\]

(Faraday’s law)
(Maxwell–Ampère law)
(Gauss’s law)
(Gauss’s law – magnetic)

where \( \mathbf{E} \) is the electric field intensity, \( \mathbf{D} \) is the electric flux density, \( \mathbf{H} \) is the magnetic field intensity, \( \mathbf{B} \) is the magnetic flux density, \( \mathbf{j} \) is the electric current density, and \( \rho \) is the electric charge density. Often the “optical” problem is analyzed, i.e. the situation when the cavity is not driven (cold mode), hence \( \mathbf{j} \) and \( \rho \) are assumed to vanish.

Again by separating variables, i.e. assuming a time harmonic behavior of the fields, e.g.,

\[ \mathbf{E}(x, t) = \mathbf{e}(x)e^{i\omega t}, \]

and by using the constitutive relations

\[ \mathbf{D} = \varepsilon \mathbf{E}, \quad \mathbf{B} = \mu \mathbf{H}, \quad \mathbf{j} = \sigma \mathbf{E}, \]

Table 1.2: Numerical solutions of acoustic vibration problem

![Fourth eigenmode of the acoustic vibration problem](image-url)
one obtains after elimination of the magnetic field intensity the so-called time-harmonic Maxwell equations

\[ \text{curl } \mu^{-1} \text{curl } e(x) = \lambda \varepsilon e(x), \quad x \in \Omega, \]
(1.68)
\[ \text{div } \varepsilon e(x) = 0, \quad x \in \Omega, \]
\[ n \times e = 0, \quad x \in \partial \Omega. \]

Here, additionally, the cavity boundary \( \partial \Omega \) is assumed to be perfectly electrically conducting, i.e., \( E(x,t) \times n(x) = 0 \) for \( x \in \partial \Omega \).

The eigenvalue problem (1.68) is a constrained eigenvalue problem. Only functions are taken into account that are divergence-free. This constraint is enforced by Lagrange multipliers. A weak formulation of the problem is then

\[
\text{Find } (\lambda, e, p) \in \mathbb{R} \times H_0(\text{curl}; \Omega) \times H_0^1(\Omega) \text{ such that } e \neq 0 \text{ and }
\]
(a) \( (\mu^{-1} \text{curl } e, \text{curl } \Psi) + (\text{grad } p, \Psi) = \lambda (\varepsilon e, \Psi), \quad \forall \Psi \in H_0(\text{curl}; \Omega), \)
(b) \( (e, \text{grad } q) = 0, \quad \forall q \in H_0^1(\Omega). \)

With the correct finite element discretization this problem turns in a matrix eigenvalue problem of the form

\[
\begin{bmatrix}
A & C \\
C^T & O
\end{bmatrix}
\begin{bmatrix}
x \\
y
\end{bmatrix}
= \lambda
\begin{bmatrix}
M & O \\
O & O
\end{bmatrix}
\begin{bmatrix}
x \\
y
\end{bmatrix}.
\]

The solution of this matrix eigenvalue problem corresponds to vibrating electric fields. A possible shape of domain \( \Omega \) is given in Figure 1.11.

Figure 1.11: Comet cavity of Paul Scherrer Institute

1.8 Spectral clustering\(^3\)

The goal of clustering is to group a given set of data points \( x_1, \ldots, x_n \) into \( k \) clusters such that members from the same cluster are (in some sense) close to each other and members from different clusters are (in some sense) well separated from each other.

\(^3\)This section is based on a tutorial by von Luxburg [12]. Thanks to Daniel Kressner for compiling it!
A popular approach to clustering is based on similarity graphs. For this purpose, we need to assume some notion of similarity \( s(x_i, x_j) \geq 0 \) between pairs of data points \( x_i \) and \( x_j \). An undirected graph \( G = (V, E) \) is constructed such that its vertices correspond to the data points: \( V = \{x_1, \ldots, x_n\} \). Two vertices \( x_i, x_j \) are connected by an edge if the similarity \( s_{ij} \) between \( x_i \) and \( x_j \) is sufficiently large. Moreover, a weight \( w_{ij} > 0 \) is assigned to the edge, depending on \( s_{ij} \). If two vertices are not connected we set \( w_{ij} = 0 \).

The weights are collected into a weighted adjacency matrix

\[
W = (w_{ij})_{i,j=1}^n.
\]

There are several possibilities to define the weights of the similarity graph associated with a set of data points and a similarity function:

**fully connected graph** All points with positive similarity are connected with each other and we simply set \( w_{ij} = s(x_i, x_j) \). Usually, this will only result in reasonable clusters if the similarity function models locality very well. One example of such a similarity function is the Gaussian

\[
s(x_i, x_j) = \exp\left(-\frac{\|x_i - x_j\|^2}{2\sigma^2}\right),
\]

where \( \|x_i - x_j\| \) is some distance measure (e.g., Euclidean distance) and \( \sigma \) is some parameter controlling how strongly locality is enforced.

**k-nearest neighbors** Two vertices \( x_i, x_j \) are connected if \( x_i \) is among the \( k \)-nearest neighbors of \( x_j \) or if \( x_j \) is among the \( k \)-nearest neighbors of \( x_i \) (in the sense of some distance measure). The weight of the edge between connected vertices \( x_i, x_j \) is set to the similarity function \( s(x_i, x_j) \).

**\( \varepsilon \)-neighbors** Two vertices \( x_i, x_j \) are connected if their pairwise distance is smaller than \( \varepsilon \) for some parameter \( \varepsilon > 0 \). In this case, the weights are usually chosen uniformly, e.g., \( w_{ij} = 1 \) if \( x_i, x_j \) are connected and \( w_{ij} = 0 \) otherwise.

Assuming that the similarity function is symmetric \( (s(x_i, x_j) = s(x_j, x_i) \) for all \( x_i, x_j \)) all definitions above give rise to a symmetric weight matrix \( W \). In practice, the choice of the most appropriate definition depends – as usual – on the application.

### 1.8.1 The graph Laplacian

In the following we construct the so called graph Laplacian, whose spectral decomposition will later be used to determine clusters. For simplicity, we assume the weight matrix \( W \) to be symmetric. The degree of a vertex \( x_i \) is defined as

\[
d_i = \sum_{j=1}^n w_{ij}.
\]

In the case of an unweighted graph, the degree \( d_i \) amounts to the number of vertices adjacent to \( v_i \) (counting also \( v_i \) if \( w_{ii} = 1 \)). The degree matrix is defined as

\[
D = \text{diag}(d_1, d_2, \ldots, d_n).
\]

The graph Laplacian is then defined as

\[
L = D - W.
\]

By (1.69), the row sums of \( L \) are zero. In other words, \( Le = 0 \) with \( e \) the vector of all ones. This implies that 0 is an eigenvalue of \( L \) with the associated eigenvector \( e \). Since \( L \)
is symmetric all its eigenvalues are real and one can show that 0 is the smallest eigenvalue; hence \( L \) is positive semidefinite. It may easily happen that more than one eigenvalue is zero. For example, if the set of vertices can be divided into two subsets \( \{x_1, \ldots, x_k\}, \{x_{k+1}, \ldots, x_n\} \), and vertices from one subset are not connected with vertices from the other subset, then

\[
L = \begin{pmatrix} L_1 & 0 \\ 0 & L_2 \end{pmatrix},
\]

where \( L_1, L_2 \) are the Laplacians of the two disconnected components. Thus \( L \) has two eigenvectors \( (e_0^1) \) and \( (e_0^2) \) with eigenvalue 0. Of course, any linear combination of these two linearly independent eigenvectors is also an eigenvector of \( L \).

The observation above leads to the basic idea behind spectral graph partitioning: If the vertices of the graph decompose into \( k \) connected components \( V_1, \ldots, V_k \) there are \( k \) zero eigenvalues and the associated invariant subspace is spanned by the vectors

\[
(1.71) \quad \chi_{V_1}, \chi_{V_2}, \ldots, \chi_{V_k},
\]

where \( \chi_{V_j} \) is the indicator vector having a 1 at entry \( i \) if \( x_i \in V_j \) and 0 otherwise.

### 1.8.2 Spectral clustering

On a first sight, it may seem that (1.71) solves the graph clustering problem. One simply computes the eigenvectors belonging to the \( k \) zero eigenvalues of the graph Laplacian and the zero structure (1.71) of the eigenvectors can be used to determine the vertices belonging to each component. Each component gives rise to a cluster.

This tempting idea has two flaws. First, one cannot expect the eigenvectors to have the structure (1.71). Any computational method will yield an arbitrary eigenbasis, e.g., arbitrary linear combinations of \( \chi_{V_1}, \chi_{V_2}, \ldots, \chi_{V_k} \). In general, the method will compute an orthonormal basis \( U \) with

\[
(1.72) \quad U = (v_1, \ldots, v_k)Q,
\]

where \( Q \) is an arbitrary orthogonal \( k \times k \) matrix and \( v_i = \chi_{V_j} / |V_j| \) with the cardinality \( |V_j| \) of \( V_j \). Second and more importantly, the goal of graph clustering is not to detect connected components of a graph. Requiring the components to be completely disconnected from each other is too strong and will usually not lead to a meaningful clustering. For example, when using a fully connected similarity graph only one eigenvalue will be zero and the corresponding eigenvector \( e \) yields one component, which is the graph itself! Hence, instead of computing an eigenbasis belonging to zero eigenvalues, one determines an eigenbasis belonging to the \( k \) smallest eigenvalues.

#### Example 1.1

200 real numbers are generated by superimposing samples from 4 Gaussian distributions with 4 different means:

```matlab
m = 50; randn('state',0);
x = [2+randn(m,1)/4;4+randn(m,1)/4;6+randn(m,1)/4;8+randn(m,1)/4];
```

The following two figures show the histogram of the distribution of the entries of \( x \) and the eigenvalues of the graph Laplacian for the fully connected similarity graph with similarity function \( s(x_i, x_j) = \exp \left( -\frac{|x_i - x_j|^2}{2} \right) \):

\[<\text{Figure}1>\]

There are more efficient algorithms for finding connected components, e.g., breadth-first and depth-first search.
As expected, one eigenvalue is (almost) exactly zero. Additionally, the four smallest eigenvalues have a clearly visible gap to the other eigenvalues. The following four figures show the entries of the 4 eigenvectors belonging to the 4 smallest eigenvalues of \( L \):

On the one hand, it is clearly visible that the eigenvectors are well approximated by linear combinations of indicator vectors. On the other hand, none of the eigenvectors is close to an indicator vector itself and hence no immediate conclusion on the clusters is possible.

To solve the issue that the eigenbasis (1.72) may be transformed by an arbitrary orthogonal matrix, we “transpose” the basis and consider the row vectors of \( U \):

\[
 U^T = (u_1, u_2, \ldots, u_n), \quad u_i \in \mathbb{R}^k.
\]

If \( U \) contained indicator vectors then each of the short vectors \( u_i \) would be a unit vector \( e_j \) for some \( 1 \leq j \leq k \) (possibly divided by \( |V_j| \)). In particular, the \( u_i \) would separate very well into \( k \) different clusters. The latter property does not change if the vectors \( u_i \) undergo an orthogonal transformation \( Q^T \). Hence, applying a clustering algorithm to \( u_1, \ldots, u_n \) allows us to detect the membership of \( u_i \) independent of the orthogonal transformation. The key point is that the short vectors \( u_1, \ldots, u_n \) are much better separated than the original data \( x_1, \ldots, x_n \). Hence, a much simpler algorithm can be used for clustering. One of the most basic algorithms is \textit{k-means clustering}. Initially, this algorithm assigns each \( u_i \) randomly\(^5\) to a cluster \( \ell \) with \( 1 \leq \ell \leq k \) and then iteratively proceeds as follows:

1. Compute cluster centers \( c_\ell \) as cluster means:

\[
 c_\ell = \frac{\sum_{i \text{ in cluster } \ell} u_i}{\sum_{i \text{ in cluster } \ell} 1}.
\]

2. Assign each \( u_i \) to the cluster with the nearest cluster center.

The algorithm is stopped when the assigned clusters do not change in an iteration.

\(^5\)For unlucky choices of random assignments the k-means algorithm may end up with less than \( k \) clusters. A simple albeit dissatisfying solution is to restart k-means with a different random assignment.
1.8. SPECTRAL CLUSTERING

Example 1.1 (cont’d). The \( k \)-means algorithm applied to the eigenbasis from Example 1.1 converges after 2 iterations and results in the following clustering:

![Cluster](image)

1.8.3 Normalized graph Laplacians

It is sometimes advantageous to use a normalized Laplacian

\[
D^{-1}L = I - D^{-1}W
\]

instead of the standard Laplacians. Equivalently, this means that we compute the eigenvectors belonging to the smallest eigenvalues of the generalized eigenvalue problem \( Wx = \lambda Dx \). Alternatively, one may also compute the eigenvalues from the symmetric matrix \( D^{-1/2}WD^{-1/2} \) but the eigenvectors need to be adjusted to compensate this transformation.

Example 1.1 (cont’d). The eigenvalues of the normalized Laplacian for Example 1.1 are shown below:

![Eigenvalues](image)

In comparison to the eigenvalues of the standard Laplacian, the four smallest eigenvalues of the are better separated from the rest. Otherwise, the shape of the eigenvectors is similar and the resulting clustering is identical with the one obtained with the standard Laplacian.
CHAPTER 1. INTRODUCTION

Figure 1.12: Things that can go wrong with the basic model: left is a dangling node, right a terminal strong component featuring a cyclic path. Figures are from [2]

1.9 Google’s PageRank\(^6\)

One of the reasons why Google is such an effective search engine is the PageRank that determines the importance of a web page [2, 10, 13]. The PageRank is determined entirely by the link structure of the World Wide Web. For any particular query, Google finds the pages on the Web that match that query and lists those pages in the order of their PageRank. Let’s imagine a surfer brachiate through pages of the world wide web randomly choosing an outgoing link from one page to get to the next. This can lead to dead ends at pages with no outgoing links, or cycles around cliques of interconnected pages. So, every once in a while, simply choose a random page from the Web. This theoretical random walk is known as a Markov chain or Markov process. The limiting probability that an infinitely dedicated random surfer visits any particular page is its PageRank. A page has high rank if other pages with high rank link to it.

Let \( W \) be the set of (reachable) web pages and let \( n = |W| \). On WorldWideWebSize.com\(^7\) it is estimated that Google’s index contains around to 49.5 billion pages.

The elements of the connectivity matrix \( G \in \mathbb{R}^{n \times n} \) is defined by

\[
g_{ij} = \begin{cases} 
1 & \text{there is a hyperlink } j \rightarrow i, \\
0 & \text{otherwise.}
\end{cases}
\]

Clearly, this is an extremely sparse matrix. The number of its nonzero elements \( \text{nnz}(G) \) equals the number of hyperlinks in \( W \). Let \( r_i \) and \( c_j \) be the row and column sums of \( G \),

\[
r_i = \sum_j g_{ij}, \quad c_j = \sum_i g_{ij}.
\]

Then \( r_j \) is called the in-degree and \( c_j \) is called the out-degree of the \( j \)th page. \( c_j = 0 \) means a dead end.

In Fig. 1.13 we see the example of a tiny web with just \( n = 6 \) nodes. The nodes \( \alpha, \beta, \gamma, \delta, \rho, \sigma \) correspond to labels 1 to 6 in the matrix notation, in this sequence.

\(^6\)Here we closely follow Section 2.11 in Moler’s MATLAB introduction [13].

Figure 1.13: A small web with 6 nodes.

Then the connectivity matrix for the small web is given by

$$G = \begin{bmatrix}
0 & 0 & 0 & 1 & 0 & 1 \\
1 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 \\
0 & 1 & 1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 \\
1 & 0 & 1 & 0 & 0 & 0
\end{bmatrix}.$$  

Notice the zero 5th column of $G$. This column corresponds to the dead end at the dangling node $\rho$.

Let $A$ be the matrix with elements

$$a_{ij} = \begin{cases}
g_{ij}/c_j & \text{if } c_j \neq 0 \\
1/n & \text{if } c_j = 0 \text{ (dead end)}.\end{cases}$$

In the small web example above,

$$A = \begin{bmatrix}
0 & 0 & 0 & \frac{1}{3} & \frac{1}{3} & 1 \\
\frac{1}{2} & 0 & 0 & 0 & \frac{1}{3} & 0 \\
0 & \frac{1}{3} & 0 & 0 & \frac{1}{3} & 0 \\
0 & \frac{1}{2} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\
0 & 0 & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\
\frac{1}{2} & 0 & 0 & \frac{1}{3} & 0 & \frac{1}{3} \\
\end{bmatrix}.$$  

The entries in $A$’s column $j$ indicate the probabilities of jumping from the $j$th page to the other pages on the web. Column 3, e.g., tells that starting from node 3 ($= \gamma$) nodes $\delta$, $\rho$, $\sigma$ are chosen with equal probability $1/3$. Note that we choose any page of the web with equal probability when we land at a dead end.
To not be stuck to much in parts of the web, we follow the links only with probability $\alpha$. With probability $1 - \alpha$ we choose a random page. Therefore, we replace $A$ by the matrix

$$\tilde{A} = \alpha A + (1 - \alpha) p e^T,$$

where $p$ is a personalization vector and $e = (1, 1, \ldots, 1)^T$. ($p$ has nonnegative elements that sum to 1, $\|p\|_1 = 1$.) Note that $p$ may have zero entries indicating, e.g., uncongenial, discredited, or discriminated web pages. We assume an innocent web and set $p = e/n$. Since $n \approx 5 \cdot 10^{10}$ in the real WWW, a typical entry of $p$ is about $2 \cdot 10^{-11}$.

Note that $e^T \tilde{A} = e^T$. So, $1 \in \sigma(A^T) = \sigma(A)$, i.e., 1 is an eigenvalue of $A$ with left eigenvector $e$. Since the matrix norm

$$\|A\|_1 = \max_{1 \leq j \leq n} \sum_{i=1}^n |a_{ij}| = 1,$$

$A$ cannot have an eigenvalue larger than 1 in modulus. The Perron–Frobenius theorem for matrices with nonnegative entries states that such matrices have a simple real eigenvalue of largest modulus [4]. Therefore, the eigenvalue 1 is in fact the largest eigenvalue of $A$. We are not interested in the left eigenvector $e$ but in the right eigenvector $x$,

$$x = \tilde{A} x.$$

The Perron–Frobenius theory confirms that $x$ can be chosen such that all its entries are nonnegative. If $x$ is scaled such that

$$\sum_{i=1}^n x_i = 1$$

then $x$ is the state vector of the Markov chain and is Google’s PageRank.

The computation of the PageRank amounts to determining the largest eigenvalue and corresponding eigenvector of a matrix. It can be determined by vector iteration. The computation gets easier the smaller the damping factor $\alpha$ is chosen. However, small $\alpha$ means small weight is given to the structure of the web. In [13] a MATLAB routine `pagerankpow.m` is provided to compute the PageRank exploiting the sparsity structure of $G$.

### 1.10 Other sources of eigenvalue problems

The selection of applications above may lead to the impression that eigenvalue problems in practice virtually always require the computation of the smallest eigenvalues of a symmetric matrix. This is not the case. For example, a linear stability analysis requires the computation of all eigenvalues on or close to the imaginary axis of a nonsymmetric matrix. Computational methods for decoupling the stable/unstable parts of a dynamical system require the computation of all eigenvalues in the left and/or right half of the complex plane. The principal component analysis (PCA), which plays an important role in a large variety of applications, requires the computation of the largest eigenvalues (or rather singular values). As we will see in the following chapters, the region of eigenvalues we are interested in determines the difficulty of the eigenvalue problem to a large extent (along
with the matrix order and structure. It should also guide the choice of algorithm for solving an eigenvalue problem.

Saad [14] discusses further interesting sources of eigenvalue problems like electronic structure calculations, the stability of dynamical systems, or Markov chain models similar as Google’s PageRank.

Bibliography

Chapter 2

Basics

2.1 Notation

The fields of real and complex numbers are denoted by $\mathbb{R}$ and $\mathbb{C}$, respectively. Elements in $\mathbb{R}$ and $\mathbb{C}$, scalars, are denoted by lowercase letters, $a, b, c, \ldots$, and $\alpha, \beta, \gamma, \ldots$

Vectors are denoted by boldface lowercase letters, $a, b, c, \ldots$, and $\alpha, \beta, \gamma, \ldots$ We denote the space of vectors of $n$ real components by $\mathbb{R}^n$ and the space of vectors of $n$ complex components by $\mathbb{C}^n$.

\[
\mathbf{x} \in \mathbb{R}^n \iff \mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}, \quad x_i \in \mathbb{R}.
\]

We often make statements that hold for real or complex vectors or matrices. Then we write, e.g., $\mathbf{x} \in \mathbb{F}^n$.

The inner product of two $n$-vectors in $\mathbb{C}$ is defined as

\[
(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{n} x_i \bar{y}_i = \mathbf{y}^* \mathbf{x},
\]

that is, we require linearity in the first component and anti-linearity in the second.

$\mathbf{y}^* = (\bar{y}_1, \bar{y}_2, \ldots, \bar{y}_n)$ denotes conjugate transposition of complex vectors. To simplify notation we denote real transposition by an asterisk as well.

Two vectors $\mathbf{x}$ and $\mathbf{y}$ are called orthogonal, $\mathbf{x} \perp \mathbf{y}$, if $\mathbf{x}^* \mathbf{y} = 0$.

The inner product (2.2) induces a norm in $\mathbb{F}$,

\[
\|\mathbf{x}\| = \sqrt{(\mathbf{x}, \mathbf{x})} = \left( \sum_{i=1}^{n} |x_i|^2 \right)^{1/2}.
\]

This norm is often called Euclidean norm or 2-norm.

The set of $m$-by-$n$ matrices with components in the field $\mathbb{F}$ is denoted by $\mathbb{F}^{m \times n}$,

\[
A \in \mathbb{F}^{m \times n} \iff A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}, \quad a_{ij} \in \mathbb{F}.
\]
The matrix \( A^* \in \mathbb{F}^{n \times m} \),

\[
A^* = \begin{pmatrix}
\bar{a}_{11} & \bar{a}_{21} & \ldots & \bar{a}_{m1} \\
\bar{a}_{12} & \bar{a}_{22} & \ldots & \bar{a}_{m2} \\
\vdots & \vdots & \ddots & \vdots \\
\bar{a}_{1n} & \bar{a}_{2n} & \ldots & \bar{a}_{nm}
\end{pmatrix}
\]

is the **Hermitian transpose** of \( A \). Notice, that with this notation \( n \)-vectors can be identified with \( n \)-by-1 matrices.

The following classes of square matrices are of particular importance:

- \( A \in \mathbb{F}^{n \times n} \) is called **Hermitian** if and only if \( A^* = A \).
- A **real** Hermitian matrix is called **symmetric**.
- \( U \in \mathbb{F}^{n \times n} \) is called **unitary** if and only if \( U^{-1} = U^* \).
- **Real** unitary matrices are called **orthogonal**.
- \( A \in \mathbb{F}^{n \times n} \) is called **normal** if \( A^*A = AA^* \). Both, Hermitian and unitary matrices are normal.

We define the norm of a matrix to be the norm induced by the vector norm (2.3),

\[
\|A\| := \max_{x \neq 0} \frac{\|Ax\|}{\|x\|} = \max_{\|x\|=1} \|Ax\|.
\]

The condition number of a nonsingular matrix is defined as \( \kappa(A) = \|A\|\|A^{-1}\| \). It is easy to show that if \( U \) is unitary then \( \|Ux\| = \|x\| \) for all \( x \). Thus the condition number of a unitary matrix is 1.

### 2.2 Statement of the problem

The **(standard) eigenvalue problem** is as follows.

Given a square matrix \( A \in \mathbb{F}^{n \times n} \).
Find scalars \( \lambda \in \mathbb{C} \) and vectors \( x \in \mathbb{C}^n \), \( x \neq 0 \), such that

\[
Ax = \lambda x,
\]

i.e., such that

\[
(A - \lambda I)x = 0
\]

has a nontrivial (nonzero) solution.

So, we are looking for numbers \( \lambda \) such that \( A - \lambda I \) is **singular**.

**Definition 2.1** Let the pair \( (\lambda, x) \) be a solution of (2.7) or (2.8), respectively. Then

- \( \lambda \) is called an **eigenvalue** of \( A \),
- \( x \) is called an **eigenvector** corresponding to \( \lambda \)
2.2. STATEMENT OF THE PROBLEM

- \((\lambda, x)\) is called eigenpair of \(A\).
- The set \(\sigma(A)\) of all eigenvalues of \(A\) is called spectrum of \(A\).
- The set of all eigenvectors corresponding to an eigenvalue \(\lambda\) together with the vector 0 form a linear subspace of \(\mathbb{C}^n\) called the eigenspace of \(\lambda\). As the eigenspace of \(\lambda\) is the null space of \(\lambda I - A\) we denote it by \(\mathcal{N}(\lambda I - A)\).
- The dimension of \(\mathcal{N}(\lambda I - A)\) is called geometric multiplicity \(g(\lambda)\) of \(\lambda\).
- An eigenvalue \(\lambda\) is a zero of the characteristic polynomial
  \[\chi(\lambda) := \det(\lambda I - A) = \lambda^n + a_{n-1}\lambda^{n-1} + \cdots + a_0.\]
  The multiplicity of \(\lambda\) as a zero of \(\chi\) is called the algebraic multiplicity \(m(\lambda)\) of \(\lambda\).
  We will later see that
  \[1 \leq g(\lambda) \leq m(\lambda) \leq n, \quad \lambda \in \sigma(A), \quad A \in \mathbb{F}^{n \times n}.\]

Remark 2.1. A nontrivial solution solution \(y\) of
\[
y^* A = \lambda y^*
\]
is called left eigenvector corresponding to \(\lambda\). A left eigenvector of \(A\) is a right eigenvector of \(A^*\), corresponding to the eigenvalue \(\bar{\lambda}\), \(A^* y = \bar{\lambda} y\). \(\square\)

Problem 2.2 Let \(x\) be a (right) eigenvector of \(A\) corresponding to an eigenvalue \(\lambda\) and let \(y\) be a left eigenvector of \(A\) corresponding to a different eigenvalue \(\mu \neq \lambda\). Show that \(x^* y = 0\).

Remark 2.2. Let \(A\) be an upper triangular matrix,
\[
A = \begin{pmatrix}
a_{11} & a_{12} & \cdots & a_{1n} \\
a_{21} & a_{22} & \cdots & a_{2n} \\
& \ddots & \ddots & \ddots \\
& & & a_{nn}
\end{pmatrix}, \quad a_{ik} = 0 \text{ for } i > k.
\]
Then we have
\[\det(\lambda I - A) = \prod_{i=1}^{n} (\lambda - a_{ii}).\]
\(\square\)

Problem 2.3 Let \(\lambda = a_{ii}, 1 \leq i \leq n\), be an eigenvalue of \(A\) in (2.10). Can you give a corresponding eigenvector? Can you detect a situation where \(g(\lambda) < m(\lambda)\)?

The (generalized) eigenvalue problem is as follows.

Given two square matrices \(A, B \in \mathbb{F}^{n \times n}\). Find scalars \(\lambda \in \mathbb{C}\) and vectors \(x \in \mathbb{C}, x \neq 0\), such that
\[
(2.11) \quad Ax = \lambda Bx,
\]
or, equivalently, such that
\[
(2.12) \quad (A - \lambda B)x = 0
\]
has a nontrivial solution.
CHAPTER 2. BASICS

Definition 2.4 Let the pair \((\lambda, x)\) be a solution of (2.11) or (2.12), respectively. Then

- \(\lambda\) is called an eigenvalue of \(A\) relative to \(B\),
- \(x\) is called an eigenvector of \(A\) relative to \(B\) corresponding to \(\lambda\).
- \((\lambda, x)\) is called an eigenpair of \(A\) relative to \(B\),
- The set \(\sigma(A; B)\) of all eigenvalues of (2.11) is called the spectrum of \(A\) relative to \(B\).

Let us look at some examples.

1. Let \(B\) be nonsingular. Then

\[
Ax = \lambda Bx \iff B^{-1}Ax = \lambda x
\]

2. Let both \(A\) and \(B\) be Hermitian, \(A = A^*\) and \(B = B^*\). Let further be \(B\) positive definite and \(B = LL^*\) be its Cholesky factorization. Then

\[
Ax = \lambda Bx \iff L^{-1}AL^{-*}y = \lambda y, \quad y = L^*x.
\]

3. Let \(A\) be invertible. Then \(Ax = 0\) implies \(x = 0\). That is, \(0 \notin \sigma(A; B)\). Therefore,

\[
Ax = \lambda Bx \iff \mu x = A^{-1}Bx, \quad \mu = \frac{1}{\lambda}
\]

4. Let \(A = B \in \mathbb{R}^{n \times n}\) be invertible. Then

\[
Ax = \lambda Bx \iff B^{-1}Ax = Ix = x.
\]

Therefore, \(\sigma(A; B) = \{1\}\). The associated eigenspace is \(\mathbb{R}^n\). Every nonzero vector \(x\) is an eigenvector.

- **Difficult situation:** both \(A\) and \(B\) are singular.
  1. Let, e.g.,

\[
A = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.
\]

Then,

\[
Ae_2 = 0 = 0 \cdot Be_2 = 0 \cdot e_2,
\]

such that 0 is an eigenvalue of \(A\) relative to \(B\). Since

\[
Ae_1 = e_1 = \lambda Be_1 = \lambda 0
\]

\(e_1\) cannot be an eigenvector of \(A\) relative to \(B\).

As in (2.15) we may swap the roles of \(A\) and \(B\). Then

\[
Be_1 = 0 = \mu Ae_1 = 0e_1.
\]

So, \(\mu = 0\) is an eigenvalue of \(B\) relative to \(A\). We therefore say, informally, that \(\lambda = \infty\) is an eigenvalue of \(A\) relative to \(B\). So, \(\sigma(A; B) = \{0, \infty\}\).

2. Let

\[
A = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = A.
\]

Then,

\[
Ae_1 = 1 \cdot Be_1,
\]

\[
Ae_2 = 0 = \lambda Be_2 = \lambda 0, \quad \text{for all } \lambda \in \mathbb{C}.
\]

Therefore, in this case, \(\sigma(A; B) = \mathbb{C}\).
2.3. SIMILARITY TRANSFORMATIONS

2.3 Similarity transformations

Definition 2.5 A matrix \( A \in \mathbb{F}^{n \times n} \) is similar to a matrix \( C \in \mathbb{F}^{n \times n} \), \( A \sim C \), if and only if there is a nonsingular matrix \( S \) such that

\[
S^{-1}AS = C.
\]

The mapping \( A \mapsto S^{-1}AS \) is called a similarity transformation.

Theorem 2.6 Similar matrices have equal eigenvalues with equal multiplicities. If \((\lambda, x)\) is an eigenpair of \( A \) and \( C = S^{-1}AS \) then \((\lambda, S^{-1}x)\) is an eigenpair of \( C \).

Proof. \( Ax = \lambda x \) and \( C = S^{-1}AS \) imply that

\[
CS^{-1}x = S^{-1}ASS^{-1}x = S^{-1}\lambda x.
\]

Hence, \( A \) and \( C \) have equal eigenvalues and their geometric multiplicity is not changed by the similarity transformation. From

\[
\det(\lambda I - C) = \det(\lambda S^{-1}S - S^{-1}AS)
\]

\[
= \det(S^{-1}(\lambda I - A)S) = \det(S^{-1}) \det(\lambda I - A) \det(S) = \det(\lambda I - A)
\]

it follows that the characteristic polynomials of \( A \) and \( C \) are equal and hence also the algebraic eigenvalue multiplicities are equal.

Similarity transformations are used to transform matrices into similar matrices from which eigenvalues can be easily read. Diagonal matrices are the preferred matrix structure. However, not all matrices are diagonalizable. There is, e.g., no invertible matrix \( S \) that diagonalizes the matrix

\[
\begin{bmatrix}
1 & 1 \\
0 & 1
\end{bmatrix}.
\]

In the Jordan normal form introduced in section 2.8 the transformation is into a bidiagonal matrix. In the Schur normal form, see section 2.4 the transformation is into an upper tridiagonal matrix, but with an unitary \( S \).

Definition 2.7 Two matrices \( A \) and \( B \) are called unitarily similar if \( S \) in (2.16) is unitary. If the matrices are real the term orthogonally similar is used.

Unitary similarity transformations are very important in numerical computations. Let \( U \) be unitary. Then \( \|U\| = \|U^{-1}\| = 1 \), the condition number of \( U \) is therefore \( \kappa(U) = 1 \). Hence, if \( C = U^{-1}AU \) then \( C = U^*AU \) and \( \|C\| = \|A\| \). In particular, if \( A \) is disturbed by \( \delta A \) (e.g., roundoff errors introduced when storing the entries of \( A \) in finite-precision arithmetic) then

\[
U^*(A + \delta A)U = C + \delta C, \quad \|\delta C\| = \|\delta A\|.
\]

Hence, errors (perturbations) in \( A \) are not amplified by a unitary similarity transformation. This is in contrast to arbitrary similarity transformations. However, as we will see later, small eigenvalues may still suffer from large relative errors.

Another reason for the importance of unitary similarity transformations is the preservation of symmetry: If \( A \) is symmetric then \( U^{-1}AU = U^*AU \) is symmetric as well.

For generalized eigenvalue problems, similarity transformations are not so crucial since we can operate with different matrices from both sides. If \( S \) and \( T \) are nonsingular

\[
Ax = \lambda Bx \iff TAS^{-1}Sx = \lambda TBS^{-1}Sx.
\]
CHAPTER 2. BASICS

This sometimes called equivalence transformation of $A, B$. Thus, $\sigma(A; B) = \sigma(TAS^{-1}; TBS^{-1})$.

Let us consider a special case: let $B$ be invertible and let $B = LU$ be the LU-factorization of $B$. Then we set $S = U$ and $T = L^{-1}$ and obtain $TBU^{-1} = L^{-1}LUU^{-1} = I$. Thus, $\sigma(A; B) = \sigma(L^{-1}AU^{-1}; I) = \sigma(L^{-1}AU^{-1})$.

2.4 Schur decomposition

**Theorem 2.8 (Schur decomposition)** If $A \in \mathbb{C}^{n \times n}$ then there is a unitary matrix $U \in \mathbb{C}^{n \times n}$ such that

$$U^*AU = T$$

is upper triangular. The diagonal elements of $T$ are the eigenvalues of $A$.

**Proof.** The proof is by induction. For $n = 1$, the theorem is obviously true.

Assume that the theorem holds for matrices of order $\leq n - 1$. Let $(\lambda, x), \|x\| = 1$, be an eigenpair of $A$, $Ax = \lambda x$. We construct a unitary matrix $U_1$ with first column $x$ (e.g. the Householder reflector $U_1$ with $U_1x = e_1$). Partition $U_1 = [x, \bar{U}]$. Then

$$U_1^*AU_1 = \begin{bmatrix} x^*Ax & x^*AU \end{bmatrix} \begin{bmatrix} \bar{U}^*Ax & \bar{U}^*AU \end{bmatrix} = \begin{bmatrix} \lambda & \cdots & \times & \times \\ 0 & \ddots & & \\ \times & & \ddots & \ddots \\ \times & & \times & \ddots & \ddots \\ \end{bmatrix}$$

as $Ax = \lambda x$ and $\bar{U}^*x = 0$ by construction of $U_1$. By assumption, there exists a unitary matrix $\hat{U} \in \mathbb{C}^{(n-1) \times (n-1)}$ such that $\hat{U}^*\hat{AU} = \hat{T}$ is upper triangular. Setting $U := U_1(1 \oplus \hat{U})$, we obtain (2.17).

Notice, that this proof is not constructive as we assume the knowledge of an eigenpair $(\lambda, x)$. So, we cannot employ it to actually compute the Schur form. The QR algorithm is used for this purpose. We will discuss this basic algorithm in Chapter 4.

Let $U^*AU = T$ be a Schur decomposition of $A$ with $U = [u_1, u_2, \ldots, u_n]$. The Schur decomposition can be written as $AU = UT$. The $k$-th column of this equation is

$$A u_k = \lambda u_k + \sum_{i=1}^{k-1} t_{ik} u_i, \quad \lambda_k = t_{kk}.$$  

This implies that

$$A u_k \in \text{span}\{u_1, \ldots, u_k\}, \quad \forall k.$$  

Thus, the first $k$ **Schur vectors** $u_1, \ldots, u_k$ form an invariant subspace\(^1\) for $A$. From (2.18) it is clear that the first Schur vector is an eigenvector of $A$. The other columns of $U$, however, are in general not eigenvectors of $A$. Notice, that the Schur decomposition is not unique. In the proof we have chosen any eigenvalue $\lambda$. This indicates that the eigenvalues can be arranged in any order in the diagonal of $T$. This also indicates that the order with which the eigenvalues appear on $T$’s diagonal can be manipulated.

**Problem 2.9** Let

$$A = \begin{bmatrix} \lambda_1 & \alpha \\ 0 & \lambda_2 \end{bmatrix}.$$  

\(^1\)A subspace $V \subset \mathbb{F}^n$ is called invariant for $A$ if $AV \subset V$.  

Find an orthogonal $2 \times 2$ matrix $Q$ such that

$$Q^*AQ = \begin{bmatrix} \lambda_2 & \beta \\ 0 & \lambda_1 \end{bmatrix}.$$ 

Hint: the first column of $Q$ must be a normalized eigenvector of $A$ corresponding to eigenvalue $\lambda_2$. Why?

### 2.5 The real Schur decomposition

Real matrices can have complex eigenvalues. If complex eigenvalues exist, then they occur in complex conjugate pairs! That is, if $\lambda$ is an eigenvalue of the real matrix $A$, then also $\bar{\lambda}$ is an eigenvalue of $A$. The following theorem indicates that complex computation can be avoided.

**Theorem 2.10 (Real Schur decomposition)** If $A \in \mathbb{R}^{n \times n}$ then there is an orthogonal matrix $Q \in \mathbb{R}^{n \times n}$ such that

$$(2.20) \quad Q^T AQ = 
\begin{bmatrix}
R_{11} & R_{12} & \cdots & R_{1m} \\
R_{21} & R_{22} & \cdots & R_{2m} \\
\vdots & \vdots & \ddots & \vdots \\
R_{m1} & R_{m2} & \cdots & R_{mm}
\end{bmatrix}$$

is upper quasi-triangular. The diagonal blocks $R_{ii}$ are either $1 \times 1$ or $2 \times 2$ matrices. A $1 \times 1$ block corresponds to a real eigenvalue, a $2 \times 2$ block corresponds to a pair of complex conjugate eigenvalues.

**Remark 2.3.** The matrix

$$\begin{bmatrix}
\alpha & \beta \\
-\beta & \alpha
\end{bmatrix}, \quad \alpha, \beta \in \mathbb{R},$$

has the eigenvalues $\alpha + i\beta$ and $\alpha - i\beta$.

**Proof.** Let $\lambda = \alpha + i\beta$, $\beta \neq 0$, be an eigenvalue of $A$ with eigenvector $x = u + iv$. Then $\bar{\lambda} = \alpha - i\beta$ is an eigenvalue corresponding to $\bar{x} = u - iv$. To see this we first observe that

$$A x = A(u + iv) = A u + i A v,$$

$$\lambda x = (\alpha + i\beta)(u + iv) = (\alpha u - \beta v) + i(\beta u + \alpha v).$$

Thus,

$$A \bar{x} = A(u - iv) = A u - i A v,$$

$$= (\alpha u - \beta v) - i(\beta u + \alpha v)$$

$$= (\alpha - i\beta)u - i(\alpha - i\beta)v = (\alpha - i\beta)(u - iv) = \bar{\lambda} \bar{x}.$$ 

Now, the actual proof starts. Let $k$ be the number of complex conjugate pairs. We prove the theorem by induction on $k$.

First we consider the case $k = 0$. In this case $A$ has real eigenvalues and eigenvectors. It is clear that we can repeat the proof of the Schur decomposition of Theorem 2.8 in real arithmetic to get the decomposition (2.17) with $U \in \mathbb{R}^{n \times n}$ and $T \in \mathbb{R}^{n \times n}$. So, there are $n$ diagonal blocks $R_{ij}$ in (2.20) all of which are $1 \times 1$.

Let us now assume that the theorem is true for all matrices with fewer than $k$ complex conjugate pairs. Then, with $\lambda = \alpha + i\beta$, $\beta \neq 0$ and $x = u + iv$, as previously, we have

$$A[u, v] = [u, v] \begin{bmatrix} \alpha & \beta \\ -\beta & \alpha \end{bmatrix}.$$
CHAPTER 2. BASICS

Let \( \{x_1, x_2\} \) be an orthonormal basis of \( \text{span}(\{u, v\}) \). Then, since \( u \) and \( v \) are linearly independent\(^2\), there is a nonsingular \( 2 \times 2 \) real square matrix \( C \) with

\[
[x_1, x_2] = [u, v]C.
\]

Now,

\[
A[x_1, x_2] = A[u, v]C = A[u, v] \begin{bmatrix} \alpha & \beta \\ -\beta & \alpha \end{bmatrix} C = [x_1, x_2]C^{-1} \begin{bmatrix} \alpha & \beta \\ -\beta & \alpha \end{bmatrix} C =: [x_1, x_2]S.
\]

\( S \) and \( \begin{bmatrix} \alpha & \beta \\ -\beta & \alpha \end{bmatrix} \) are similar and therefore have equal eigenvalues. Now we construct an orthogonal matrix \( [x_1, x_2, x_3, \ldots, x_n] =: [x_1, x_2, W] \). Then

\[
[x_1, x_2, W]^T A[x_1, x_2, W] = \begin{bmatrix} x_1^T \\ x_2^T \\ W^T \end{bmatrix} [x_1, x_2]S, AW = \begin{bmatrix} S & [x_1, x_2]^T AW \\ O & W^T AW \end{bmatrix}.
\]

The matrix \( W^T AW \) has less than \( k \) complex-conjugate eigenvalue pairs. Therefore, by the induction assumption, there is an orthogonal \( Q_2 \in \mathbb{R}^{(n-2) \times (n-2)} \) such that the matrix

\[
Q_2^T (W^T AW) Q_2
\]

is quasi-triangular. Thus, the orthogonal matrix

\[
Q = [x_1, x_2, x_3, \ldots, x_n] \begin{pmatrix} I_2 & O \\ O & Q_2 \end{pmatrix}
\]

transforms \( A \) similarly to quasi-triangular form. \( \blacksquare \)

2.6 Normal matrices

**Definition 2.11** A matrix \( A \in \mathbb{R}^{n \times n} \) is called normal if

\[
(2.21) \quad AA^* = A^*A.
\]

Let \( A = URU^* \) be the Schur decomposition of \( A \). Then,

\[
RR^* = U^*AUU^*A^*U = U^*A^*AU = U^*A^*UU^*AU = R^*R.
\]

Therefore, also the upper triangular \( R \) is normal. We look at the \((1,1)\)-elements of \( RR^* \) and \( R^*R \) that evidently must be equal. On one hand we have

\[
(R^*R)_{11} = \bar{r}_{11} r_{11} = |r_{11}|^2,
\]

on the other hand

\[
(RR^*)_{11} = \sum_{j=1}^n r_{1j} \bar{r}_{1j} = |r_{11}|^2 + \sum_{j=2}^n |r_{1j}|^2.
\]

Therefore, the latter sum must vanish, i.e., \( r_{1j} = 0 \) for \( j = 2, \ldots, n \). Comparing the \((2,2)\)-elements, \((3,3)\)-elements, etc., of \( RR^* \) and \( R^*R \), we see that \( R \) is diagonal. In this way we arrive at

**Theorem 2.12** A matrix is normal if and only if it is diagonalizable by a unitary matrix. \( \blacksquare \)

(Note that unitarily diagonalizable matrices are trivially normal.\(^3\))

\( ^2\)If \( u \) and \( v \) were linearly dependent then it follows that \( \beta \) must be zero.
2.7 Hermitian matrices

Definition 2.13 A matrix $A \in \mathbb{F}^{n \times n}$ is Hermitian if

$$A = A^*.$$  

The Schur decomposition for Hermitian matrices is particularly simple. We first note that $A$ being Hermitian implies that the upper triangular $\Lambda$ in the Schur decomposition $A = U \Lambda U^*$ is Hermitian and thus diagonal. In fact, because

$$\overline{\Lambda} = \Lambda^* = (U^* A U)^* = U^* A^* U = U^* A U = \Lambda,$$

each diagonal element $\lambda_i$ of $\Lambda$ satisfies $\overline{\lambda_i} = \lambda_i$. So, $\Lambda$ has to be real. In summary have the following result.

Theorem 2.14 (Spectral theorem for Hermitian matrices) Let $A$ be Hermitian. Then there is a unitary matrix $U$ and a real diagonal matrix $\Lambda$ such that

$$A = U \Lambda U^* = \sum_{i=1}^{n} \lambda_i u_i u_i^*.$$  

The columns $u_1, \ldots, u_n$ of $U$ are eigenvectors corresponding to the eigenvalues $\lambda_1, \ldots, \lambda_n$. They form an orthonormal basis for $\mathbb{F}^n$.

The decomposition (2.23) is called a spectral decomposition of $A$.

As the eigenvalues are real we can sort them with respect to their magnitude. We can, e.g., arrange them in ascending order such that $\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n$.

If $\lambda_i = \lambda_j$, then any nonzero linear combination of $u_i$ and $u_j$ is an eigenvector corresponding to $\lambda_i$,

$$A(u_i \alpha + u_j \beta) = u_i \lambda_i \alpha + u_j \lambda_j \beta = (u_i \alpha + u_j \beta) \lambda_i.$$  

However, eigenvectors corresponding to different eigenvalues are orthogonal. Let $Au = u\lambda$ and $Av = v\mu$, $\lambda \neq \mu$. Then

$$\lambda u^* v = (u^* A) v = u^* (A v) = u^* v \mu,$$

and thus

$$(\lambda - \mu) u^* v = 0,$$

from which we deduce $u^* v = 0$ as $\lambda \neq \mu$.

In summary, the eigenvectors corresponding to a particular eigenvalue $\lambda$ form a subspace, the eigenspace $\{x \in \mathbb{F}^n, Ax = \lambda x\} = \mathcal{N}(A - \lambda I)$. They are perpendicular to the eigenvectors corresponding to all the other eigenvalues. Therefore, the spectral decomposition (2.23) is unique up to $\pm$ signs if all the eigenvalues of $A$ are distinct. In case of multiple eigenvalues, we are free to choose any orthonormal basis for the corresponding eigenspace.

Remark 2.4. The notion of Hermitian or symmetric has a wider background. Let $\langle x, y \rangle$ be an inner product on $\mathbb{F}^n$. Then a matrix $A$ is symmetric with respect to this inner product if $\langle Ax, y \rangle = \langle x, Ay \rangle$ for all vectors $x$ and $y$. For the ordinary Euclidean inner product $\langle x, y \rangle = x^* y$ we arrive at the element-wise Definition 2.7 if we set $x$ and $y$ equal to coordinate vectors.

It is important to note that all the properties of Hermitian matrices that we will derive subsequently hold similarly for matrices symmetric with respect to a certain inner product.
Example 2.15 We consider the one-dimensional Sturm-Liouville eigenvalue problem

\[(2.24)\]
\[-u''(x) = \lambda u(x), \quad 0 < x < \pi, \quad u(0) = u(\pi) = 0,\]

that models the vibration of a homogeneous string of length \(\pi\) that is fixed at both ends. The eigenvalues and eigenvectors or eigenfunctions of \((2.24)\) are

\[\lambda_k = k^2, \quad u_k(x) = \sin kx, \quad k \in \mathbb{N}.\]

Let \(u_i^{(n)}\) denote the approximation of an (eigen)function \(u\) at the grid point \(x_i\),

\[u_i \approx u(x_i), \quad x_i = ih, \quad 0 \leq i \leq n + 1, \quad h = \frac{\pi}{n + 1}.\]

We approximate the second derivative of \(u\) at the interior grid points by finite differences \[3, 7\]

\[(2.25)\]
\[
\frac{1}{h^2}(-u_{i-1} + 2u_i - u_{i+1}) = \lambda u_i, \quad 1 \leq i \leq n.
\]

Collecting these equations and taking into account the boundary conditions, \(u_0 = 0\) and \(u_{n+1} = 0\), we get a (matrix) eigenvalue problem

\[(2.26)\]
\[T_n x = \lambda x\]

where

\[T_n := \frac{(n + 1)^2}{\pi^2} \begin{bmatrix}
2 & -1 & & & & \\
-1 & 2 & -1 & & & \\
& -1 & 2 & -1 & & \\
& & \ddots & \ddots & \ddots & \\
& & & -1 & 2 & -1 \\
& & & & -1 & 2
\end{bmatrix} \in \mathbb{R}^{n \times n}.
\]

The matrix eigenvalue problem \((2.26)\) can be solved explicitly \[9, p.229\]. Eigenvalues and eigenvectors are given by

\[(2.27)\]
\[\lambda_k^{(n)} = \frac{(n + 1)^2}{\pi^2} (2 - 2 \cos \phi_k) = \frac{4(n + 1)^2}{\pi^2} \sin^2 \frac{k\pi}{2(n + 1)},\]
\[u_k^{(n)} = \left( \frac{2}{n + 1} \right)^{1/2} [\sin \phi_k, \sin 2\phi_k, \ldots, \sin n\phi_k]^T, \quad \phi_k = \frac{k\pi}{n + 1}.
\]

Clearly, \(\lambda_k^{(n)}\) converges to \(\lambda_k\) as \(n \to \infty\). (Note that \(\sin \xi \to \xi\) as \(\xi \to 0\).) When we identify \(u_k^{(n)}\) with the piecewise linear function that takes on the values given by \(u_k^{(n)}\) at the grid points \(x_i\) then this function evidently converges to \(\sin kx\).

Let \(p(\lambda)\) be a polynomial of degree \(d\), \(p(\lambda) = \alpha_0 + \alpha_1\lambda + \alpha_2\lambda^2 + \cdots + \alpha_d\lambda^d\). As \(A^j = (UAU^*)^j = UA^jU^*\) we can define a matrix polynomial as

\[(2.28)\]
\[p(A) = \sum_{j=0}^d \alpha_j A^j = \sum_{j=0}^d \alpha_j U A^j U^* = U \left( \sum_{j=0}^d \alpha_j \Lambda_j \right) U^*.
\]

This equation shows that \(p(A)\) has the same eigenvectors as the original matrix \(A\). The eigenvalues are modified though, \(\lambda_k\) becomes \(p(\lambda_k)\). Similarly, more complicated functions of \(A\) can be computed if the function is defined on spectrum of \(A\).
2.8. THE JORDAN NORMAL FORM

2.8 The Jordan normal form

Theorem 2.16 (Jordan normal form) For every $A \in \mathbb{F}^{n \times n}$ there is a nonsingular matrix $X \in \mathbb{F}^{n \times n}$ such that

\begin{equation}
X^{-1}AX = J = \text{diag}(J_1, J_2, \ldots, J_p),
\end{equation}

where

\begin{equation}
J_k = J_{m_k}(\lambda_k) = \begin{bmatrix}
\lambda_k & 1 \\
& \ddots & \ddots \\
& & \lambda_k \\
& & & 1
\end{bmatrix} \in \mathbb{F}^{m_k \times m_k}
\end{equation}

are called Jordan blocks and $m_1 + \cdots + m_p = n$. The values $\lambda_k$ need not be distinct. The Jordan matrix $J$ is unique up to the ordering of the blocks. The transformation matrix $X$ is not unique.

A matrix is diagonalizable if all Jordan blocks are $1 \times 1$, i.e., $m_k = 1$ for all $k$. In this case the columns of $X$ are eigenvectors of $A$.

More generally, there is one eigenvector associated with each Jordan block, e.g.,

\[ J_2(\lambda)e_1 = \begin{bmatrix} \lambda \\ 0 \end{bmatrix} \begin{bmatrix} 1 \\ 0 \end{bmatrix} = \lambda e_1. \]

Nontrivial Jordan blocks give rise to so-called generalized eigenvectors $e_2, \ldots, e_{m_k}$ since

\[ (J_k(\lambda) - \lambda I)e_{j+1} = e_j, \quad j = 1, \ldots, m_k - 1. \]

This choice of generalized eigenvectors is not unique though, as $(J_k(\lambda) - \lambda I)(e_2 + \alpha e_1) = e_1$ for any $\alpha$. This is one of the reasons for the non-uniqueness of the transformation matrix $X$ in Theorem 2.16.

From the Jordan blocks we can read geometric and algebraic multiplicity of an eigenvalue: The number of Jordan blocks associated with a particular eigenvalue give the geometric multiplicity; the sum of its orders gives the algebraic multiplicity.

Numerically the size of the Jordan blocks cannot be determined stably as the following example shows. Let

\[ \begin{bmatrix} \varepsilon & 1 \\ 0 & -\varepsilon \end{bmatrix} \approx \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} = J_2(0) \]

be the approximation for $J_2(0)$ that some numerical algorithm has computed. This matrix has two distinct eigenvalues and thus two eigenvectors,

\[ \begin{bmatrix} \varepsilon & 1 \\ 0 & -\varepsilon \end{bmatrix} \begin{bmatrix} 1 \\ 1 \\ 1 \\ 0 \end{bmatrix} = \begin{bmatrix} \varepsilon & 1 \\ 0 & -2\varepsilon \end{bmatrix} \begin{bmatrix} \varepsilon \\ 0 \end{bmatrix}. \]

For small $\varepsilon$ the two eigenvectors are very close. They even collaps when $\varepsilon \to 0$. A numerical code cannot differ between the two cases ($\varepsilon = 0, \varepsilon \neq 0$) that have a completely different structure.

\footnote{1 \times 1 Jordan blocks are called trivial.}
Let $Y := X^{-*}$ and let $X = [X_1, X_2, \ldots, X_p]$ and $Y = [Y_1, Y_2, \ldots, Y_p]$ be partitioned according to $J$ in (2.29), meaning that $X_j, Y_j \in \mathbb{F}^{m_j \times m_j}$. Then,

\[(2.31) \quad A = X J Y^* = \sum_{k=1}^{p} X_k J_k Y_k^* = \sum_{k=1}^{p} (\lambda_k X_k Y_k^* + X_k N_k Y_k^*),\]

where $N_k = J_{m_k}(0)$. If $m_k = 1$ then $N_k$ is zero. We define the matrices $P_k := X_k Y_k^*$ and $D_k := X_k N_k Y_k^*$. Then, since $P_k^2 = P_k$, $P_k$ is a projector on $\mathcal{R}(P_k) = \mathcal{R}(X_k)$. It is called a \textit{spectral projector}. From (2.31) we immediately obtain

\[(2.32) \quad A = \sum_{k=1}^{p} (\lambda_k P_k + D_k).\]

Since $I_{m_k} N_k = N_k I_{m_k} = N_k$, we have

\[
\begin{align*}
P_k D_\ell &= D_\ell P_k = \delta_{k\ell} D_\ell, \\
A P_k &= P_k A = P_k A P_k = \lambda_k P_k + D_k, \\
A^j P_k &= P_k A^j = P_k A^j P_k = P_k (\lambda_k I_n + D_k)^j = (\lambda_k I_n + D_k)^j P_k.
\end{align*}
\]

The Jordan normal form can be computed from the Schur decomposition $A = U^* T U$, see, e.g., [2], although it is not recommended in general to do so.

1. Group equal eigenvalues on the diagonal of the triangular $T$. This is a generalization of the solution of Problem 2.4.

2. Let

\[(2.33) \quad T = \begin{bmatrix} T_1 & T_{12} & \cdots & T_{1s} \\ T_2 & \cdots & T_{2s} \\ \vdots & & \ddots & \vdots \\ T_s & & & T_s \end{bmatrix},\]

where the $s$ diagonal blocks $T_k$ are related to the $s$ distinct eigenvalues of $T$. The off-diagonal blocks $T_{j\ell}$ are zeroed one after the other. Each steps requires the solution of a \textit{Sylvester equation} $T_{j\ell} = T_j Y - Y T_\ell$.

\textbf{Exercise:} Consider the case of two (simple or multiple) eigenvalues,

\[T = \begin{bmatrix} T_1 & T_{12} \\ T_2 & T_2 \end{bmatrix}.\]

Apply a similarity transformation with the matrix

\[X = \begin{bmatrix} I_1 & Y \\ I_2 & I_2 \end{bmatrix}.\]

Determine $Y$? How can this be extended to the case (2.33) with $s$ diagonal blocks?

3. The diagonal blocks $T_1, \ldots, T_s$ are brought to Jordan form.

The Jordan normal form can be nicely employed to define matrix functions, see [5].
2.9. PROJECTIONS

2.9 Projections

Definition 2.17 A matrix $P$ that satisfies

\begin{equation}
    P^2 = P
\end{equation}

is called a projection.

Obviously, a projection is a square matrix. If $P$ is a projection then $Px = x$ for all $x$ in the range $\mathcal{R}(P)$ of $P$. In fact, if $x \in \mathcal{R}(P)$ then $x = Py$ for some $y \in \mathbb{F}^n$ and $Px = P(Py) = P^2y = Py = x$.

Example 2.18 Let

\[
P = \begin{pmatrix} 1 & 2 \\ 0 & 0 \end{pmatrix}.
\]

The range of $P$ is $\mathcal{R}(P) = \mathbb{F} \times \{0\}$. The effect of $P$ is depicted in Figure 2.1: All points $x$ that lie on a line parallel to span\{$(2, -1)^*$\} are mapped on the same point on the $x_1$ axis. So, the projection is along span\{$(2, -1)^*$\} which is the null space $\mathcal{N}(P)$ of $P$.

Example 2.19 Let $x$ and $y$ be arbitrary vectors such that $y^*x \neq 0$. Then

\begin{equation}
    P = \frac{xy^*}{y^*y}
\end{equation}

is a projection. Notice that the projector of the previous example can be expressed in the form (2.35).

Problem 2.20 Let $X, Y \in \mathbb{F}^{n \times p}$ such that $Y^*X$ is nonsingular. Show that

\[
P := X(Y^*X)^{-1}Y^*
\]

is a projection.

Example 2.21 The spectral projectors $X_kY_k^*$ introduced in (2.31) are projectors. Their range is the span of all eigenvectors and generalized eigenvectors associated with the eigenvalue $\lambda_k$. 
If \( P \) is a projection then \( I - P \) is a projection as well. In fact, \((I - P)^2 = I - 2P + P^2 = I - 2P + P = I - P\). If \( Px = 0 \) then \((I - P)x = x\). Therefore, the range of \( I - P \) coincides with the null space of \( P \), \( \mathcal{R}(I - P) = \mathcal{N}(P) \). It can be shown that \( \mathcal{R}(P) = \mathcal{N}(P^*)^\perp \).

Notice that \( \mathcal{R}(P) \cap \mathcal{R}(I - P) = \mathcal{N}(I - P) \cap \mathcal{N}(P) = \{0\} \). For, if \( Px = 0 \) then \((I - P)x = x\), which can only be zero if \( x = 0 \). So, any vector \( x \) can be uniquely decomposed into

\[
(2.36) \quad x = x_1 + x_2, \quad x_1 \in \mathcal{R}(P), \quad x_2 \in \mathcal{R}(I - P) = \mathcal{N}(P).
\]

The most interesting situation occurs if the decomposition is orthogonal, i.e., if \( x_1^*x_2 = 0 \) for all \( x \).

**Definition 2.22** A matrix \( P \) is called an **orthogonal projection** if

\[
(2.37) \quad (i) \quad P^2 = P, \\
(ii) \quad P^* = P.
\]

**Proposition 2.23** Let \( P \) be a projection. Then the following statements are equivalent.

(i) \( P^* = P \),

(ii) \( \mathcal{R}(I - P) \perp \mathcal{R}(P) \), i.e., \((Px)^*(I - P)y = 0 \) for all \( x,y \).

**Proof.** (ii) follows trivially from (i) and (2.34).

Now, let us assume that (ii) holds. Then

\[
x^*P^*y = (Px)^*y = (Px)^*(Py + (I - P)y) \\
= (Px)^*(Py) \\
= (Px + (I - P)x)(Py) = x^*(Py).
\]

This equality holds for any \( x \) and \( y \) and thus implies (i). \( \blacksquare \)

**Example 2.24** Let \( q \) be an arbitrary vector of norm 1, \( \|q\| = q^*q = 1 \). Then \( P = qq^* \) is the orthogonal projection onto \( \text{span}\{q\} \).

**Example 2.25** Let \( Q \in \mathbb{F}^{n \times p} \) with \( Q^*Q = I_p \). Then \( QQ^* \) is the orthogonal projector onto \( \mathcal{R}(Q) \), which is the space spanned by the columns of \( Q \).

**Problem 2.26** Let \( Q, Q_1 \in \mathbb{F}^{n \times p} \) with \( Q^*Q = Q_1^*Q_1 = I_p \) such that \( \mathcal{R}(Q) = \mathcal{R}(Q_1) \). This means that the columns of \( Q \) and \( Q_1 \), respectively, are orthonormal bases of the same subspace of \( \mathbb{F}^n \). Show that the projector does not depend on the basis of the subspace, i.e., that \( QQ^* = Q_1Q_1^* \).

**Problem 2.27** Let \( Q = [Q_1, Q_2] \), \( Q_1 \in \mathbb{F}^{n \times p}, \ Q_2 \in \mathbb{F}^{n \times (n - p)} \) be a unitary matrix. \( Q_1 \) contains the first \( p \) columns of \( Q \), \( Q_2 \) the last \( n - p \). Show that \( Q_1Q_1^* + Q_2Q_2^* = I \). Hint: Use \( QQ^* = I \). Notice, that if \( P = Q_1Q_1^* \) then \( I - P = Q_2Q_2^* \).

**Problem 2.28** What is the form of the orthogonal projection onto \( \text{span}\{q\} \) if the inner product is defined as \( \langle x, y \rangle := y^*Mx \) where \( M \) is a symmetric positive definite matrix?
2.10. THE RAYLEIGH QUOTIENT

2.10 The Rayleigh quotient

Definition 2.29 The quotient

\[ \rho(x) := \frac{x^*Ax}{x^*x}, \quad x \neq 0, \]

is called the Rayleigh quotient of \( A \) at \( x \).

Notice, that \( \rho(ax) = \rho(x), \alpha \neq 0 \). Hence, the properties of the Rayleigh quotient can be investigated by just considering its values on the unit sphere. Using the spectral decomposition \( A = U\Lambda U^* \), we get

\[ x^*Ax = x^*U\Lambda^*U^*x = \sum_{i=1}^{n} \lambda_i |u_i^*x|^2. \]

Similarly, \( x^*x = \sum_{i=1}^{n} |u_i^*x|^2 \). With \( \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n \), we have

\[ \lambda_1 \sum_{i=1}^{n} |u_i^*x|^2 \leq \sum_{i=1}^{n} \lambda_i |u_i^*x|^2 \leq \lambda_n \sum_{i=1}^{n} |u_i^*x|^2. \]

So,

\[ \lambda_1 \leq \rho(x) \leq \lambda_n, \quad \text{for all } x \neq 0. \]

As

\[ \rho(u_k) = \lambda_k, \]

the extremal values \( \lambda_1 \) and \( \lambda_n \) are actually attained for \( x = u_1 \) and \( x = u_n \), respectively. Thus we have proved the following theorem.

Theorem 2.30 Let \( A \) be Hermitian. Then the Rayleigh quotient satisfies

(2.38) \[ \lambda_1 = \min_x \rho(x), \quad \lambda_n = \max_x \rho(x). \]

As the Rayleigh quotient is a continuous function it attains all values in the closed interval \([\lambda_1, \lambda_n]\).

The next theorem generalizes the above theorem to interior eigenvalues. The following theorems is attributed to Poincaré, Fischer and Pólya.

Theorem 2.31 (Minimum-maximum principle) Let \( A \) be Hermitian. Then

(2.39) \[ \lambda_p = \min_{X \in \mathbb{F}^{n \times p}, \text{ rank}(X) = p} \max_{x \neq 0} \rho(Xx) \]

Proof. Let \( U_{p-1} = [u_1, \ldots, u_{p-1}] \). For every \( X \in \mathbb{F}^{n \times p} \) with full rank we can choose \( x \neq 0 \) such that \( U_{p-1}^*Xx = 0 \). Then \( 0 \neq z := Xx = \sum_{i=p}^{n} z_i u_i \). As in the proof of the previous theorem we obtain the inequality

\[ \rho(z) \geq \lambda_p. \]

To prove that equality holds in (2.39) we choose \( X = [u_1, \ldots, u_p] \), then

\[ U_{p-1}^*Xx = \begin{bmatrix} 1 & 0 & \cdots & 0 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & 1 & 0 \end{bmatrix} x = 0 \]

implies that \( x = e_p \), i.e., that \( z = Xx = u_p \). So, \( \rho(z) = \lambda_p \).

An important consequence of the minimum-maximum principle is the following
Theorem 2.32 (Monotonicity principle) Let \( A \) be Hermitian and let \( q_1, \ldots, q_p \) be normalized, mutually orthogonal vectors. Set \( Q := [q_1, \ldots, q_p] \) and \( A' := Q^*AQ \in \mathbb{F}^{p \times p} \). Then the \( p \) eigenvalues \( \lambda'_1 \leq \cdots \leq \lambda'_p \) of \( A' \) satisfy
\[
\lambda_k \leq \lambda'_k, \quad 1 \leq k \leq p.
\]

Proof. Let \( w_1, \ldots, w_p \in \mathbb{F}^p \) be the eigenvectors of \( A' \),
\[
A'w_i = \lambda'_iw_i, \quad 1 \leq i \leq p,
\]
with \( w_i^*w_j = \delta_{ij} \). Then the vectors \( Qw_1, \ldots, Qw_p \) are normalized and mutually orthogonal. Therefore, we can construct a normalized vector \( x_0 \) with \( \|x_0\| = 1 \),
\[
x_0 := a_1Qw_1 + \cdots + a_kw_k = Q(a_1w_1 + \cdots + a_kw_k) = Qa,
\]
that is orthogonal to the first \( k - 1 \) eigenvectors of \( A \),
\[
x_0^*u_i = 0, \quad 1 \leq i \leq k - 1.
\]
(Note, that \( \|x_0\| = 1 \) implies \( \|a\| = 1 \).) Then, with the minimum-maximum principle we get
\[
\lambda_k = \min_{x \neq 0} \frac{R(x)}{x^*u_1 = \cdots = x^*u_{k-1} = 0} \leq \lambda'_k \leq \lambda_{k+1}.
\]

Exercise: It is possible to prove the inequalities (2.40) without assuming that the \( q_1, \ldots, q_p \) are orthonormal. But then one has to use the eigenvalues \( \lambda'_k \) of \( A'x = \lambda'Bx, \quad B' = Q^*Q \), instead of (2.41). Prove this.

Remark 2.5. Let \( q_i = e_{j_i}, \quad 1 \leq i \leq k \). This means that we extract rows and columns \( j_1, \ldots, j_k \) to construct \( A' \). (The indices \( j_i \) are assumed to be distinct.)

Remark 2.6. Let’s remove a single row/column (with equal index) from \( A \). Then \( k = n - 1 \) in Remark 2.5 and the index set \( j_1, \ldots, j_{n-1} \) contains all but one of the integers \( 1, \ldots, n \).

If we formulate a monotonicity principle based on the eigenvalues \( \lambda_n, \lambda_{n-1}, \ldots \) as consecutive maxima of the Rayleigh quotient, then we arrive at the interlacing property
\[
\lambda_k \leq \lambda'_k \leq \lambda_{k+1}, \quad 1 \leq k < n.
\]
This interlacing property can be generalized, see, e.g., [6, 4].

The trace of a matrix \( A \in \mathbb{F}^{n \times n} \) is defined to be the sum of the diagonal elements of a matrix. Matrices that are similar have equal trace. Hence, by the spectral theorem,
\[
\text{trace}(A) = \sum_{i=1}^{n} a_{ii} = \sum_{i=1}^{n} \lambda_i.
\]
The following theorem is proved in a similar way as the minimum-maximum theorem.

Theorem 2.33 (Trace theorem)
\[
\lambda_1 + \lambda_2 + \cdots + \lambda_p = \min_{X \in \mathbb{F}^{n \times p}, \ X^*X = I_p} \text{trace}(X^*AX)
\]
2.11 Cholesky factorization

**Definition 2.34** A Hermitian matrix is called **positive definite** (positive semi-definite) if all its eigenvalues are positive (nonnegative).

For a Hermitian positive definite matrix $A$, the LU decomposition can be written in a particular form reflecting the symmetry of $A$.

**Theorem 2.35 (Cholesky factorization)** Let $A \in \mathbb{F}^{n \times n}$ be Hermitian positive definite. Then there is a lower triangular matrix $L$ such that

$$A = LL^*.$$  

$L$ is unique if we choose its diagonal elements to be positive.

**Proof.** We prove the theorem by giving an algorithm that computes the desired factorization.

Since $A$ is positive definite, we have $a_{11} = \langle e_1, Ae_1 \rangle > 0$. Therefore we can form the matrix

$$L_1 = \begin{bmatrix} l^{(1)}_{11} & \cdots & 1 \\ l^{(1)}_{12} & \cdots & 1 \\ \vdots & \ddots & \vdots \\ l^{(1)}_{1n} & \cdots & 1 \end{bmatrix} = \begin{bmatrix} \sqrt{a_{11}} & \cdots & 1 \\ \frac{a_{21}}{\sqrt{a_{11}}} & \cdots & 1 \\ \vdots & \ddots & \vdots \\ \frac{a_{n1}}{\sqrt{a_{11}}} & \cdots & 1 \end{bmatrix}.$$  

We now form the matrix

$$A_1 = L_1^{-1}AL_1^{-1*} = \begin{bmatrix} 1 & 0 & \cdots & 0 \\ 0 & a_{22} - \frac{a_{21}a_{12}}{a_{11}} & \cdots & \frac{a_{21}a_{1n}}{a_{11}} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & a_{n2} - \frac{a_{n1}a_{12}}{a_{11}} & \cdots & a_{nn} - \frac{a_{n1}a_{1n}}{a_{11}} \end{bmatrix}.$$  

This is the first step of the algorithm. Since positive definiteness is preserved by a congruence transformation $X^*AX$ (see also Theorem 2.37 below), $A_1$ is again positive definite. Hence, we can proceed in a similar fashion factorizing $A_1(2:n,2:n)$, etc.

Collecting $L_1, L_2, \ldots$, we obtain

$$I = L_n^{-1} \cdots L_2^{-1}L_1^{-1}A(L_1^*)^{-1}(L_2^*)^{-1} \cdots (L_n^*)^{-1}$$  

or

$$(L_1L_2 \cdots L_n)(L_n^* \cdots L_2^*L_1^*) = A,$$

which is the desired result. It is easy to see that $L_1L_2 \cdots L_n$ is a triangular matrix and that

$$L_1L_2 \cdots L_n = \begin{bmatrix} l^{(1)}_{11} & \cdots & l^{(1)}_{1n} \\ l^{(2)}_{11} & \cdots & l^{(2)}_{1n} \\ \vdots & \ddots & \vdots \\ l^{(n)}_{11} & \cdots & l^{(n)}_{1n} \end{bmatrix}.$$  

**Remark 2.7.** When working with symmetric matrices, one often stores only half of the matrix, e.g. the lower triangle consisting of all elements including and below the diagonal. The $L$-factor of the Cholesky factorization can overwrite this information in-place to save memory. □
Definition 2.36 The inertia of a Hermitian matrix is the triple $(\nu, \zeta, \pi)$ where $\nu, \zeta, \pi$ is the number of negative, zero, and positive eigenvalues.

Theorem 2.37 (Sylvester’s law of inertia) If $A \in \mathbb{C}^{n \times n}$ is Hermitian and $X \in \mathbb{C}^{n \times n}$ is nonsingular then $A$ and $X^*AX$ have the same inertia.

\textbf{Proof.} The proof is given, for example, in [4]. \qed

Remark 2.8. Two matrices $A$ and $B$ are called congruent if there is a nonsingular matrix $X$ such that $B = X^*AX$. Thus, Sylvester’s law of inertia can be stated in the following form: The inertia is invariant under congruence transformations. \qed

2.12 The singular value decomposition (SVD)

Theorem 2.38 (Singular value decomposition) If $A \in \mathbb{C}^{m \times n}$ then there exist unitary matrices $U \in \mathbb{C}^{m \times m}$ and $V \in \mathbb{C}^{n \times n}$ such that

\begin{equation}
U^*AV = \Sigma = \begin{pmatrix}
\text{diag}(\sigma_1, \ldots, \sigma_p) & 0 \\
0 & 0
\end{pmatrix}, \quad p = \min(m, n),
\end{equation}

where $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_p \geq 0$.

\textbf{Proof.} If $A = O$, the theorem holds with $U = I_m, V = I_n$ and $\Sigma$ equal to the $m \times n$ zero matrix.

We now assume that $A \neq O$. Let $x, \|x\| = 1$, be a vector that maximizes $\|Ax\|$ and let $Ax = \sigma y$ where $\sigma = \|A\| = \|Ax\|$ and $\|y\| = 1$. As $A \neq O, \sigma > 0$. Consider the scalar function

\[ f(\alpha) := \frac{\|A(x + \alpha y)\|^2}{\|x + \alpha y\|^2} = \frac{(x + \alpha y)^*A^*A(x + \alpha y)}{(x + \alpha y)^*(x + \alpha y)}. \]

Because of the extremality of $Ax$, the derivative $f'(\alpha)$ of $f(\alpha)$ must vanish at $\alpha = 0$. This holds for all $y!$ We have

\[ \frac{df}{d\alpha}(\alpha) \bigg|_{\alpha=0} = \frac{x^*A^*Ay + \alpha y^*A^*Ay\|x + \alpha y\|^2 - (x^*y + \alpha y^*y)\|A(x + \alpha y)\|^2}{\|x + \alpha y\|^4} = 0. \]

Thus, we have for all $y$,

\[ \frac{df}{d\alpha}(\alpha) \bigg|_{\alpha=0} = \frac{x^*A^*Ay\|x\|^2 - x^*y\|A(x)\|^2}{\|x\|^4} = 0. \]

As $\|x\| = 1$ and $\|Ax\| = \sigma$, we have

\[ (x^*A^*A - \sigma^2 x^*)y = (A^*Ax - \sigma^2 x)^*y = 0, \quad \text{for all } y, \]

from which

\[ A^*Ax = \sigma^2 x \]

follow. Multiplying $Ax = \sigma y$ from the left by $A^*$ we get $A^*Ax = \sigma A^*y = \sigma^2 x$ from which

\[ A^*y = \sigma x \]

and $AA^*y = \sigma Ax = \sigma^2 y$ follows. Therefore, $x$ is an eigenvector of $A^*A$ corresponding to the eigenvalue $\sigma^2$ and $y$ is an eigenvector of $AA^*$ corresponding to the same eigenvalue.
Now, we construct a unitary matrix $U_1$ with first column $y$ and a unitary matrix $V_1$ with first column $x$, $U_1 = [y, \hat{U}]$ and $V_1 = [x, \hat{V}]$. Then

$$U_1^* A V_1 = \begin{bmatrix} y^* A x & y^* A \hat{V} \end{bmatrix} = \begin{bmatrix} \sigma & \sigma x^* \hat{V} \\ \sigma U^* y & \sigma U^* \hat{V} \end{bmatrix} = \begin{bmatrix} \sigma & 0^* \\ 0 & A \end{bmatrix}$$

where $\hat{A} = U^* A \hat{V}$.

The proof above is due to W. Gragg. It nicely shows the relation of the singular value decomposition with the spectral decomposition of the Hermitian matrices $A^* A$ and $AA^*$,

(2.47) \hspace{1cm} A = U \Sigma V^* \implies A^* A = V \Sigma^2 V^*, \hspace{1cm} AA^* = U \Sigma^2 U^*,

Newton methods

3.1 Linear and nonlinear eigenvalue problems

In **linear** eigenvalue problems we have to find values $\lambda \in \mathbb{C}$ such that $\lambda I - A$ is **singular**. Here $A \in \mathbb{F}^{n \times n}$ is a given real or complex matrix. Equivalently, we have to find values $\lambda \in \mathbb{C}$ such that there is a nontrivial (nonzero) $x$ that satisfies

$$ (A - \lambda I)x = 0 \iff Ax = \lambda x. \quad (3.1) $$

In the linear eigenvalue problem (3.1) the eigenvalue $\lambda$ appears linearly. However, as the unknown $\lambda$ is multiplied with the unknown vector $x$, the problem is in fact nonlinear. We have $n+1$ unknowns $\lambda, x_1, \ldots, x_n$ that are not uniquely defined by the $n$ equations in (3.1). We have noticed earlier, that the **length** of the eigenvector $x$ is not determined. This can be rectified by adding a further equation that fixes the length of $x$. The straightforward condition is

$$ \|x\|^2 = x^*x = 1, \quad (3.2) $$

that determines $x$ up to a complex scalar of modulus 1, in the real case $\pm 1$. Another condition to normalize $x$ is by requesting that

$$ c^Tx = 1, \quad \text{for some } c. \quad (3.3) $$

Eq. (3.3) is linear in $x$ and thus simpler. However, the combined equations (3.1)–(3.3) are nonlinear anyway. Furthermore, $c$ must be chosen such that it has a strong component in the (unknown) direction of the searched eigenvector. This requires some knowledge about the solution.

In **nonlinear** eigenvalue problems we have to find values $\lambda \in \mathbb{C}$ such that

$$ A(\lambda)x = 0 \quad (3.4) $$

where $A(\lambda)$ is a matrix the elements of which depend on $\lambda$ in a nonlinear way. An example is a matrix polynomial,

$$ A(\lambda) = \sum_{k=0}^{d} \lambda^k A_k, \quad A_k \in \mathbb{F}^{n \times n}. \quad (3.5) $$

The linear eigenvalue problem (3.1) is a special case with $d = 1$,

$$ A(\lambda) = A_0 - \lambda A_1, \quad A_0 = A, \quad A_1 = I. $$
Chapter 3. Newton Methods

Quadratic eigenvalue problems of the form

\[(3.6)\]

\[Ax + \lambda Kx + \lambda^2 Mx = 0.\]

Matrix polynomials can be linearized, i.e., they can be transformed in a linear eigenvalue problem of bigger size. The quadratic eigenvalue problem \((3.6)\) can be transformed in a linear eigenvalue problem of size \(2n\). Setting \(y = \lambda x\) we get

\[
\begin{pmatrix}
A & O \\
O & I
\end{pmatrix}
\begin{pmatrix}
x \\
y
\end{pmatrix}
= \lambda
\begin{pmatrix}
-K & -M \\
I & O
\end{pmatrix}
\begin{pmatrix}
x \\
y
\end{pmatrix}
\]

or

\[
\begin{pmatrix}
A & K \\
O & I
\end{pmatrix}
\begin{pmatrix}
x \\
y
\end{pmatrix}
= \lambda
\begin{pmatrix}
O & -M \\
I & O
\end{pmatrix}
\begin{pmatrix}
x \\
y
\end{pmatrix}.
\]

Notice that many other linearizations are possible \([2, 6]\). Notice also the relation with the transformation of high order to first order ODE’s \([5, \text{p. 478}]\).

Instead of looking at the nonlinear system \((3.1)\) (complemented with \((3.3)\) or \((3.2)\)) we may look at the nonlinear scalar equation

\[(3.7)\]

\[f(\lambda) := \det A(\lambda) = 0\]

and apply some zero finder. Here the question arises how to compute \(f(\lambda)\) and in particular \(f'(\lambda) = \frac{d}{d\lambda} \det A(\lambda)\).

3.2 Zeros of the determinant

We first consider the computation of eigenvalues and subsequently eigenvectors by means of computing zeros of the determinant \(\det(A(\lambda))\).

Gaussian elimination with partial pivoting (GEPP) applied to \(A(\lambda)\) provides the decomposition

\[(3.8)\]

\[P(\lambda)A(\lambda) = L(\lambda)U(\lambda),\]

where \(P(\lambda)\) is the permutation matrix due to partial pivoting, \(L(\lambda)\) is a lower unit triangular matrix, and \(U(\lambda)\) is an upper triangular matrix. From well-known properties of the determinant function, equation \((3.8)\) gives

\[
\det P(\lambda) \cdot \det A(\lambda) = \det L(\lambda) \cdot \det U(\lambda).
\]

Taking the particular structures of the factors in \((3.8)\) into account, we get

\[(3.9)\]

\[f(\lambda) = \det A(\lambda) = \pm 1 \cdot \prod_{i=1}^{n} u_{ii}(\lambda).
\]

The derivative of \(\det A(\lambda)\) is

\[(3.10)\]

\[f'(\lambda) = \pm 1 \cdot \sum_{i=1}^{n} \frac{u'_{ii}(\lambda)}{u_{ii}(\lambda)} \prod_{j \neq i}^{n} u_{jj}(\lambda) = \pm 1 \cdot \sum_{i=1}^{n} \frac{u'_{ii}(\lambda)}{u_{ii}(\lambda)} f(\lambda).
\]

How can we compute the derivatives \(u'_{ii}\) of the diagonal elements of \(U(\lambda)\)?
3.2. **ZEROS OF THE DETERMINANT**

3.2.1 **Algorithmic differentiation**

A clever way to compute derivatives of a function is by *algorithmic differentiation*, see e.g., [1]. Here we assume that we have an algorithm available that computes the value $f(\lambda)$ of a function $f$, given the input argument $\lambda$. By algorithmic differentiation a new algorithm is obtained that computes besides $f(\lambda)$ the derivative $f'(\lambda)$.

The idea is easily explained by means of the Horner scheme to evaluate polynomials. Let

$$f(z) = \sum_{i=1}^{n} c_i z^i,$$

be a polynomial of degree $n$. $f(z)$ can be written in the form

$$f(z) = c_0 + z (c_1 + z (c_2 + \cdots + z (c_n \cdots)))$$

which gives rise to the recurrence

$$p_n := c_n,$$

$$p_i := z p_{i+1} + c_i, \quad i = n-1, n-2, \ldots, 0,$$

$$f(z) := p_0.$$ 

Note that each of the $p_i$ can be considered as a function (polynomial) in $z$. We use the above recurrence to determine the derivatives $dp_i$,

$$dp_n := 0, \quad p_n := c_n,$$

$$dp_i := p_{i+1} + z dp_{i+1}, \quad p_i := z p_{i+1} + c_i, \quad i = n-1, n-2, \ldots, 0,$$

$$f'(z) := dp_0, \quad f(z) := p_0.$$ 

We can proceed in a similar fashion for computing $\det A(\lambda)$. We however need to be able to compute the derivatives $a'_{ij}$. Then, we can derive each single assignment in the GEPP algorithm.

If we restrict ourselves to the standard eigenvalue problem $A x = \lambda x$ then $A(\lambda) = A - \lambda I$. Then, $a'_{ij} = \delta_{ij}$, the Kronecker $\delta$.

3.2.2 **Hyman’s algorithm**

In a Newton iteration we have to compute the determinant for possibly many values $\lambda$. Using the factorization (3.8) leads to computational costs of $\frac{2}{3} n^3$ flops (floating point operations) for each factorization, i.e., per iteration step. If this algorithm was used to compute all eigenvalues then an excessive amount of flops would be required. Can we do better?

The strategy is to transform $A$ by a similarity transformation to a *Hessenberg matrix*, i.e., a matrix $H$ whose entries below the lower off-diagonal are zero,

$$h_{ij} = 0, \quad i > j + 1.$$ 

Any matrix $A$ can be transformed into a similar Hessenberg matrix $H$ by means of a sequence of elementary unitary matrices called *Householder transformations*. The details are given in Section 4.3.
Let \( S^* A S = H \), where \( S \) is unitary. \( S \) is the product of the just mentioned Householder transformations. Then

\[
A x = \lambda x \iff H y = \lambda y, \quad x = S y.
\]

So, \( A \) and \( H \) have equal eigenvalues (\( A \) and \( H \) are similar) and the eigenvectors are transformed by \( S \). We now assume that \( H \) is \textbf{unreduced}, i.e., \( h_{i+1,i} \neq 0 \) for all \( i \). Otherwise we can split \( H x = \lambda x \) in smaller problems.

Let \( \lambda \) be an eigenvalue of \( H \) and

\[
(H - \lambda I) x = 0,
\]

i.e., \( x \) is an eigenvector of \( H \) associated with the eigenvalue \( \lambda \). Then the last component of \( x \) cannot be zero, \( x_n \neq 0 \). The proof is by contradiction. Let \( x_n = 0 \). Then (for \( n = 4 \))

\[
\begin{pmatrix}
  h_{11} - \lambda & h_{12} & h_{13} & h_{14} \\
  h_{21} & h_{22} - \lambda & h_{23} & h_{24} \\
  h_{31} & h_{32} & h_{33} - \lambda & h_{34} \\
  h_{41} & h_{42} & h_{43} & h_{44} - \lambda
\end{pmatrix}
\begin{pmatrix}
  x_1 \\
  x_2 \\
  x_3 \\
  x_4
\end{pmatrix}
= \begin{pmatrix}
  0 \\
  0 \\
  0 \\
  0
\end{pmatrix}.
\]

The last equation reads

\[
h_{n,n-1} x_{n-1} + (h_{nn} - \lambda) \cdot 0 = 0
\]

from which \( x_{n-1} = 0 \) follows since we assumed \( h_{n,n-1} \neq 0 \). In the exact same procedure we obtain \( x_{n-2} = 0, \ldots, x_1 = 0 \). But the zero vector cannot be an eigenvector. Therefore, \( x_n \) must not be zero. Without loss of generality we can set \( x_n = 1 \).

We continue to expose the procedure with a problem size \( n = 4 \). If \( \lambda \) is an eigenvalue then there are \( x_i, 1 \leq i < n \), such that

\[
\begin{pmatrix}
  h_{11} - \lambda & h_{12} & h_{13} & h_{14} \\
  h_{21} & h_{22} - \lambda & h_{23} & h_{24} \\
  h_{31} & h_{32} & h_{33} - \lambda & h_{34} \\
  h_{41} & h_{42} & h_{43} & h_{44} - \lambda
\end{pmatrix}
\begin{pmatrix}
  x_1 \\
  x_2 \\
  x_3 \\
  1
\end{pmatrix}
= \begin{pmatrix}
  0 \\
  0 \\
  0 \\
  1
\end{pmatrix}.
\]

If \( \lambda \) is \textbf{not} an eigenvalue then we determine the \( x_i \) such that

\[
\begin{pmatrix}
  h_{11} - \lambda & h_{12} & h_{13} & h_{14} \\
  h_{21} & h_{22} - \lambda & h_{23} & h_{24} \\
  h_{31} & h_{32} & h_{33} - \lambda & h_{34} \\
  h_{41} & h_{42} & h_{43} & h_{44} - \lambda
\end{pmatrix}
\begin{pmatrix}
  x_1 \\
  x_2 \\
  x_3 \\
  1
\end{pmatrix}
= \begin{pmatrix}
  p(\lambda) \\
  0 \\
  0 \\
  0
\end{pmatrix}.
\]

We determine the \( n - 1 \) numbers \( x_{n-1}, x_{n-2}, \ldots, x_1 \) by

\[
x_i = \frac{-1}{h_{i+1,i}} ( (h_{i+1,i+1} - \lambda) x_{i+1} + h_{i+1,i+2} x_{i+2} + \cdots + h_{i+1,n} x_n ) , \quad i = n - 1, \ldots, 1.
\]

The \( x_i \) are functions of \( \lambda \), in fact, \( x_i \in \mathbb{P}_{n-i} \). The first equation in (3.13) gives

\[
(h_{1,1} - \lambda) x_1 + h_{1,2} x_2 + \cdots + h_{1,n} x_n = p(\lambda).
\]
3.2. ZEROS OF THE DETERMINANT

Eq. (3.13) can be understood by the factorization

\[
\begin{pmatrix}
  h_{11} - \lambda & h_{12} & h_{13} & h_{14} \\
  h_{21} & h_{22} - \lambda & h_{23} & h_{24} \\
  h_{32} & h_{33} - \lambda & h_{34} & \vdots \\
  h_{43} & \vdots & h_{44} - \lambda
\end{pmatrix}
\begin{pmatrix}
  1 & x_1 \\
  1 & x_2 \\
  1 & x_3 \\
  1 & x_4
\end{pmatrix}
= \begin{pmatrix}
  h_{11} - \lambda & h_{12} & h_{13} & p(\lambda) \\
  h_{21} & h_{22} - \lambda & h_{23} & 0 \\
  h_{32} & h_{33} - \lambda & h_{34} & 0 \\
  h_{43} & \vdots & h_{44} & \vdots
\end{pmatrix}.
\]

The last column of this equation corresponds to (3.13). Taking determinants yields

\[
\det(H - \lambda I) = (-1)^n \prod_{i=1}^{n-1} h_{i+1,i} p(\lambda) = c \cdot p(\lambda).
\]

So, \( p(\lambda) \) is a constant multiple of the determinant of \( H - \lambda I \). Therefore, we can solve \( p(\lambda) = 0 \) instead of \( \det(H - \lambda I) = 0 \).

Since the quantities \( x_1, x_2, \ldots, x_n \) and thus \( p(\lambda) \) are differentiable functions of \( \lambda \), we can algorithmically differentiate to get \( p'(\lambda) \).

For \( i = n - 1, \ldots, 1 \) we have

\[
x'_i = \frac{-1}{h_{i+1,i}} (-x_{i+1} + (h_{i+1,i+1} - \lambda) x'_i + h_{i+1,i+2} x'_{i+2} + \cdots + h_{i+1,n-1} x'_{n-1}).
\]

Finally,

\[
c \cdot f'(\lambda) = -x_1 + (h_{1,n} - \lambda) x'_1 + h_{1,2} x'_2 + \cdots + h_{1,n-1} x'_{n-1}.
\]

Algorithm 3.1 implements Hyman’s algorithm that returns \( p(\lambda) \) and \( p'(\lambda) \) given an input parameter \( \lambda \) [7].

**Algorithm 3.1 Hyman’s algorithm**

1: Choose a value \( \lambda \).
2: \( x_n := 1; \ dx_n := 0 \);
3: for \( i = n - 1 \) downto 1 do
4: \( s = (\lambda - h_{i+1,i+1}) x_{i+1}; \ ds = x_{i+1} + (\lambda - h_{i+1,i+1}) dx_{i+1}; \)
5: \( \text{for } j = i + 2 \text{ to } n \text{ do} \)
6: \( s = s - h_{i+1,j} x_j; \ ds = ds - h_{i+1,j} dx_j; \)
7: \( \text{end for} \)
8: \( x_i = s/h_{i+1,i}; \ dx_i = ds/h_{i+1,i}; \)
9: \( \text{end for} \)
10: \( s = (\lambda - h_{1,1}) x_1; \ ds = -x_1 - (\lambda - h_{1,1}) dx_1; \)
11: for \( i = 2 \) to \( n \) do
12: \( s = s + h_{1,i} x_i; \ ds = ds + h_{1,i} dx_i; \)
13: \( \text{end for} \)
14: \( p(\lambda) := s; \ p'(\lambda) := ds; \)

This algorithm computes \( p(\lambda) = c' \cdot \det(H(\lambda)) \) and its derivative \( p'(\lambda) \) of a Hessenberg matrix \( H \) in \( \mathcal{O}(n^2) \) operations. Inside a Newton iteration the new iterate is obtained by

\[
\lambda_{k+1} = \lambda_k - \frac{p(\lambda_k)}{p'(\lambda_k)}, \quad k = 0, 1, \ldots
\]
CHAPTER 3. NEWTON METHODS

The factor $c'$ cancels. An initial guess $\lambda_0$ has to be chosen to start the iteration. It is clear that a good guess reduces the iteration count of the Newton method. The iteration is considered converged if $f(\lambda_k) \approx 0$. The vector $x = (x_1, x_2, \ldots, x_{n-1}, 1)^T$ is a good approximation of the corresponding eigenvector.

Remark 3.1. Higher order derivatives of $f$ can be computed in an analogous fashion. Higher order zero finders (e.g. Laguerre’s zero finder) are then applicable \[3\].

3.2.3 Computing multiple zeros

If we have found a zero $z$ of $f(x) = 0$ and want to compute another one, we want to avoid recomputing the already found $z$.

We can explicitly deflate the zero by defining a new function

\[ f_1(x) := \frac{f(x)}{x - z}, \]

and apply our method of choice to $f_1$. This procedure can in particular be done with polynomials. The coefficients of $f_1$ are however very sensitive to inaccuracies in $z$. We can proceed similarly for multiple zeros $z_1, \ldots, z_m$. Explicit deflation is not recommended and often not feasible since $f$ is not given explicitly.

For the reciprocal Newton correction for $f_1$ in (3.15) we get

\[ \frac{f'_1(x)}{f_1(x)} = \frac{f'(x)}{x-z} - \frac{f(x)}{(x-z)^2} = \frac{f'(x)}{f(x)} - \frac{1}{x-z}. \]

Then a Newton correction becomes

\[ x^{(k+1)} = x_k - \frac{1}{f'(x_k)} \frac{1}{x_k - z}, \]

and similarly for multiple zeros $z_1, \ldots, z_m$. Working with (3.16) is called implicit deflation. Here, $f$ is not modified. In this way errors in $z$ are not propagated to $f_1$.

3.3 Newton methods for the constrained matrix problem

We consider the nonlinear eigenvalue problem (3.4) equipped with the normalization condition (3.3),

\[ T(\lambda)x = 0, \]
\[ c^T x = 1, \]

where $c$ is some given vector. At a solution $(x, \lambda)$, $x \neq 0$, $T(\lambda)$ is singular. Note that $x$ is defined only up to a (nonzero) multiplicative factor. $c^T x = 1$ is just a way to normalize $x$. Another one would be $\|x\|_2 = 1$, cf. the next section.

Solving (3.17) is equivalent with finding a zero of the nonlinear function $f(x, \lambda)$,

\[ f(x, \lambda) = \begin{pmatrix} T(\lambda)x \\ c^T x - 1 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \]

To apply Newton’s zero finding method we need the Jacobian of $f$,

\[ J(x, \lambda) = \frac{\partial f(x, \lambda)}{\partial (x, \lambda)} = \begin{pmatrix} T(\lambda) & T'(\lambda)x \\ c^T & 0 \end{pmatrix}. \]
Here, $T'(\lambda)$ denotes the (elementwise) derivative of $T$ with respect to $\lambda$. Then, a step of Newton’s iteration is given by

$$
(x_{k+1}, \lambda_{k+1}) = (x_k, \lambda_k) - J(x_k, \lambda_k)^{-1} f(x_k, \lambda_k),
$$

or, with the abbreviations $T_k := T(\lambda_k)$ and $T'_k := T'(\lambda_k)$,

$$
\begin{pmatrix}
T_k & T'_k x_k \\
\mu^T & 0
\end{pmatrix}
\begin{pmatrix}
x_{k+1} - x_k \\
\lambda_{k+1} - \lambda_k
\end{pmatrix} =
\begin{pmatrix}
-T_k x_k \\
1 - \mu^T x_k
\end{pmatrix}.
$$

If $x_k$ is normalized, $c^T x_k = 1$, then the second equation in (3.21) yields

$$
c^T(x_{k+1} - x_k) = 0 \iff c^T x_{k+1} = 1.
$$

The first equation in (3.21) gives

$$
T_k (x_{k+1} - x_k) + (\lambda_{k+1} - \lambda_k) T'_k x_k = -T_k x_k \iff T_k x_{k+1} = -(\lambda_{k+1} - \lambda_k) T'_k x_k.
$$

We introduce the auxiliary vector $u_{k+1}$ by

$$
T_k u_{k+1} = T'_k x_k.
$$

Note that

$$
x_{k+1} = -(\lambda_{k+1} - \lambda_k) u_{k+1}.
$$

So, $u_{k+1}$ points in the desired direction; it just needs to be normalized. Premultiplying (3.24) by $c^T$ and using (3.22) gives

$$
1 = c^T x_{k+1} = -(\lambda_{k+1} - \lambda_k) c^T u_{k+1},
$$

or

$$
(3.25) \quad \lambda_{k+1} = \lambda_k - \frac{1}{c^T u_{k+1}}.
$$

In summary, we get the following procedure.

**Algorithm 3.2 Newton iteration for solving (3.18)**

1. Choose a starting vector $x_0 \in \mathbb{R}^n$ with $c^T x_0 = 1$. Set $k := 0$.
2. repeat
   3. Solve $T(\lambda_k) u_{k+1} := T'(\lambda_k) x_k$ for $u_{k+1}$; 
   4. $\mu_k := c^T u_{k+1}$;
   5. $x_{k+1} := u_{k+1}/\mu_k$; (Normalize $u_{k+1}$)
   6. $\lambda_{k+1} := \lambda_k - 1/\mu_k$;
   7. $k := k + 1$;
8. until some convergence criterion is satisfied

If the linear eigenvalue problem is solved by Algorithm 3.3 then $T'(\lambda) x = 0$. In each iteration step a linear system has to be solved which requires the factorization of a matrix.

We now change the way we normalize $x$. Problem (3.17) becomes

$$
T(\lambda) x = 0, \quad \|x\|^2 = 1,
$$

(3.26)
with the corresponding nonlinear system of equations

\[(3.27) \quad f(x, \lambda) = \left( \begin{array}{c} T(\lambda) x \\ \frac{1}{2}(x^T x - 1) \end{array} \right) = \left( \begin{array}{c} 0 \\ 0 \end{array} \right). \]

The Jacobian now is

\[(3.28) \quad J(x, \lambda) \equiv \frac{\partial f(x, \lambda)}{\partial (x, \lambda)} = \left( \begin{array}{c} T'(\lambda) x \\ \lambda^T - \lambda \end{array} \right). \]

The Newton step (3.20) is changed into

\[(3.29) \quad \left( T_k T_k' x_k \right) \left( x_{k+1} - x_k \right) = \left( \begin{array}{c} -T_k x_k \\ \frac{1}{2}(1 - x_k^T x_k) \end{array} \right). \]

If \( x_k \) is normalized, \( \|x_k\| = 1 \), then the second equation in (3.29) gives

\[(3.30) \quad x_k^T (x_{k+1} - x_k) = 0 \iff x_k^T x_{k+1} = 1. \]

The correction \( \Delta x_k := x_{k+1} - x_k \) is orthogonal to the actual approximation. The first equation in (3.29) is the same as in (3.21). Again, we employ the auxiliary vector \( u_{k+1} \) defined in (3.23). Premultiplying (3.24) by \( x_k^T \) and using (3.30) gives

\[ 1 = x_k^T x_{k+1} = -(\lambda_{k+1} - \lambda_k) x_k^T u_{k+1}, \]

or

\[(3.31) \quad \lambda_{k+1} = \lambda_k - \frac{1}{x_k^T u_{k+1}}. \]

The next iterate \( x_{k+1} \) is obtained by normalizing \( u_{k+1} \),

\[(3.32) \quad x_{k+1} = u_{k+1}/\|u_{k+1}\|. \]

**Algorithm 3.3 Newton iteration for solving (3.27)**

1: Choose a starting vector \( x_0 \in \mathbb{R}^n \) with \( \|x^{(0)}\| = 1 \). Set \( k := 0 \).
2: repeat
3: \quad Solve \( T(\lambda_k) u_{k+1} := T'(\lambda_k) x_k \) for \( u_{k+1} \); \hspace{1cm} (3.23)
4: \quad \mu_k := x_k^T u_{k+1};
5: \quad \lambda_{k+1} := \lambda_k - 1/\mu_k; \hspace{1cm} (3.31)
6: \quad x_{k+1} := u_{k+1}/\|u_{k+1}\|; \hspace{1cm} (\text{Normalize } u_{k+1})
7: \quad k := k + 1;
8: until some convergence criterion is satisfied

### 3.4 Successive linear approximations

Ruhe [4] suggested the following method which is not derived as a Newton method. It is based on an expansion of \( T(\lambda) \) at some approximate eigenvalue \( \lambda_k \).

\[(3.33) \quad T(\lambda)x \approx (T(\lambda_k) - \vartheta T'(\lambda_k))x = 0, \quad \lambda = \lambda_k - \vartheta. \]
Algorithm 3.4  Algorithm of successive linear problems

1: Start with approximation $\lambda_1$ of an eigenvalue of $T(\lambda)$.
2: $\textbf{for } k = 1, 2, \ldots \textbf{ do}$
3:  Solve the linear eigenvalue problem $T(\lambda)u = \vartheta T'(\lambda)u$.
4:  Choose an eigenvalue $\vartheta$ smallest in modulus.
5:  $\lambda_{k+1} := \lambda_k - \vartheta$;
6: $\textbf{end for}$

Equation (3.33) is a generalized eigenvalue problem with eigenvalue $\vartheta$. If $\lambda_k$ is a good approximation of an eigenvalue, then it is straightforward to compute the smallest eigenvalue $\vartheta$ of

$$T(\lambda_k)x = \vartheta T'(\lambda_k)x$$

and update $\lambda_k$ by $\lambda_{k+1} = \lambda_k - \vartheta$.

**Remark:** If $T$ is twice continuously differentiable, and $\lambda$ is an eigenvalue of problem (1) such that $T'(\lambda)$ is singular and $0$ is an algebraically simple eigenvalue of $T'(\lambda)^{-1}T(\lambda)$, then the method in Algorithm 3.4 converges quadratically towards $\lambda$.

**Bibliography**

Chapter 4

The QR Algorithm

The QR algorithm computes a Schur decomposition of a matrix. It is certainly one of the most important algorithms in eigenvalue computations [9]. However, it is applied to dense (or: full) matrices only.

The QR algorithm consists of two separate stages. First, by means of a similarity transformation, the original matrix is transformed in a finite number of steps to Hessenberg form or – in the Hermitian/symmetric case – to real tridiagonal form. This first stage of the algorithm prepares its second stage, the actual QR iterations that are applied to the Hessenberg or tridiagonal matrix. The overall complexity (number of floating points) of the algorithm is $O(n^3)$, which we will see is not entirely trivial to obtain.

The major limitation of the QR algorithm is that already the first stage generates usually complete fill-in in general sparse matrices. It can therefore not be applied to large sparse matrices, simply because of excessive memory requirements. On the other hand, the QR algorithm computes all eigenvalues (and eventually eigenvectors) which is rarely desired in sparse matrix computations anyway.

The treatment of the QR algorithm in these lecture notes on large scale eigenvalue computation is justified in two respects. First, there are of course large or even huge dense eigenvalue problems. Second, the QR algorithm is employed in most other algorithms to solve ‘internal’ small auxiliary eigenvalue problems.

4.1 The basic QR algorithm

In 1958 Rutishauser [10] of ETH Zurich experimented with a similar algorithm that we are going to present, but based on the LR factorization, i.e., based on Gaussian elimination without pivoting. That algorithm was not successful as the LR factorization (nowadays called LU factorization) is not stable without pivoting. Francis [5] noticed that the QR factorization would be the preferred choice and devised the QR algorithm with many of the bells and whistles used nowadays.

Before presenting the complete picture, we start with a basic iteration, given in Algorithm 4.1, discuss its properties and improve on it step by step until we arrive at Francis’ algorithm.

We notice first that

$$A_k = R_k Q_k = Q_k^* A_{k-1} Q_k,$$

and hence $A_k$ and $A_{k-1}$ are unitarily similar. The matrix sequence $\{A_k\}$ converges (under certain assumptions) towards an upper triangular matrix [11]. Let us assume that the
Algorithm 4.1 Basic QR algorithm

1: Let $A \in \mathbb{C}^{n \times n}$. This algorithm computes an upper triangular matrix $T$ and a unitary matrix $U$ such that $A = UTU^*$ is the Schur decomposition of $A$.
2: Set $A_0 := A$ and $U_0 = I$.
3: for $k = 1, 2, \ldots$ do
4: $A_{k-1} := Q_k R_k$; /* QR factorization */
5: $A_k := R_k Q_k$;
6: $U_k := U_{k-1} Q_k$; /* Update transformation matrix */
7: end for
8: Set $T := A_\infty$ and $U := U_\infty$.

Eigenvalues are mutually different in magnitude and we can therefore number the eigenvalues such that $|\lambda_1| > |\lambda_2| > \cdots > |\lambda_n|$. Then – as we will show in Chapter 8 – the elements of $A_k$ below the diagonal converge to zero like

\begin{equation}
|a_{ij}^{(k)}| = \mathcal{O}(|\lambda_i/\lambda_j|^k), \quad i > j.
\end{equation}

From (4.1) we see that

\begin{equation}
A_k = Q_k^* A_{k-1} Q_k = Q_k^* Q_{k-1}^* A_{k-2} Q_{k-1} Q_k = \cdots = Q_k^* \cdots Q_1^* A_0 \underbrace{Q_1 \cdots Q_k}_{U_k}.
\end{equation}

With the same assumption on the eigenvalues, $A_k$ tends to an upper triangular matrix and $U_k$ converges to the matrix of Schur vectors.

### 4.1.1 Numerical experiments

We conduct two MATLAB experiments to illustrate the convergence rate given in (4.2). To that end, we construct a random $4 \times 4$ matrix with eigenvalues $1$, $2$, $3$, and $4$.

```matlab
D = diag([4 3 2 1]);
rand('seed',0);
format short e
S=rand(4); S = (S - .5)*2;
A = S*D/S % A_0 = A = S*D*S^{-1}
for i=1:20,
    [Q,R] = qr(A);
    end
```

This yields the matrix sequence

\[
A(0) = \begin{bmatrix}
-4.4529e-01 & 4.9063e+00 & -8.7871e-01 & 6.3036e+00 \\
-6.3941e+00 & 1.3354e+01 & 1.6668e+00 & 1.1945e+01 \\
3.6842e+00 & -6.6617e+00 & -6.8011e-02 & -7.0043e+00 \\
3.1209e+00 & -5.2052e+00 & -1.4130e+00 & -2.8484e+00 \\
\end{bmatrix},
\]

\[
A(1) = \begin{bmatrix}
5.9284e+00 & 1.6107e+00 & 9.3153e-01 & -2.2056e+01 \\
-1.5294e+00 & 1.8630e+00 & 2.0428e+00 & 6.5900e+00 \\
1.9850e-01 & 2.5660e+00 & 1.7088e+00 & 1.2184e+00 \\
2.4815e-01 & 1.5265e-01 & 2.6924e-01 & 4.9975e-01 \\
\end{bmatrix},
\]

\[
A(2) = \begin{bmatrix}
4.7396e+00 & 1.4907e+00 & -2.1236e+00 & 2.3126e+01 \\
\end{bmatrix},
\]

With the same assumption on the eigenvalues, $A_k$ tends to an upper triangular matrix and $U_k$ converges to the matrix of Schur vectors.
### 4.1. THE BASIC QR ALGORITHM

\[
\begin{bmatrix}
-4.3101e-01 & 2.4307e+00 & 2.2544e+00 & -8.2867e-01 \\
1.2803e-01 & 2.4287e+00 & 1.6852e+00 & 2.5267e+00 \\
-4.8467e-02 & -5.8164e-02 & -1.0994e-01 & 1.1899e+00 \\
\end{bmatrix}
\]

\( A(3) = \)

\[
\begin{bmatrix}
-3.9478e+00 & -2.9393e+00 & -2.9199e+00 & -2.9789e+00 \\
1.1899e+00 & 2.5267e+00 & 2.5267e+00 & 2.5267e+00 \\
-1.0994e-01 & 1.1899e+00 & 1.1899e+00 & 1.1899e+00 \\
\end{bmatrix}
\]

\[
\begin{bmatrix}
1.2803e-01 & 2.4287e-01 & 1.6852e+00 & 2.5267e+00 \\
-4.8467e-02 & -5.8164e-02 & -1.0994e-01 & 1.1899e+00 \\
1.3063e-02 & 2.2630e-02 & 7.9186e-02 & 1.2805e+00 \\
\end{bmatrix}
\]

\( A(4) = \)

\[
\begin{bmatrix}
7.6418e-01 & -5.1999e+00 & -2.9819e+00 & -2.9819e+00 \\
1.8830e+00 & 3.2484e+00 & 3.2484e+00 & 3.2484e+00 \\
3.2290e-03 & 3.2290e-03 & 3.2290e-03 & 3.2290e-03 \\
\end{bmatrix}
\]

\( A(5) = \)

\[
\begin{bmatrix}
5.2922e-01 & -6.0126e+00 & -2.2323e+00 & -2.2323e+00 \\
1.3379e+00 & 2.7694e+00 & 2.7694e+00 & 2.7694e+00 \\
1.1503e-03 & 1.1503e-03 & 1.1503e-03 & 1.1503e-03 \\
\end{bmatrix}
\]

\( A(6) = \)

\[
\begin{bmatrix}
3.6496e-01 & -6.4924e+00 & 2.2149e+01 & 2.2149e+01 \\
1.7379e+00 & 3.4935e+00 & 3.4935e+00 & 3.4935e+00 \\
3.2290e-03 & 3.2290e-03 & 3.2290e-03 & 3.2290e-03 \\
\end{bmatrix}
\]

\( A(7) = \)

\[
\begin{bmatrix}
2.5201e-01 & -6.7556e+00 & 2.2045e+00 & 2.2045e+00 \\
1.0738e+00 & 2.7694e+00 & 2.7694e+00 & 2.7694e+00 \\
1.1899e-02 & 2.9845e+00 & 2.9845e+00 & 2.9845e+00 \\
\end{bmatrix}
\]

\( A(8) = \)

\[
\begin{bmatrix}
1.7516e-01 & -6.8941e+00 & 2.1985e+01 & 2.1985e+01 \\
1.9773e+00 & 3.4935e+00 & 3.4935e+00 & 3.4935e+00 \\
3.9885e-04 & 1.1481e+00 & 1.1481e+00 & 1.1481e+00 \\
\end{bmatrix}
\]

\( A(9) = \)

\[
\begin{bmatrix}
1.2329e-01 & -6.9655e+00 & 2.1951e+01 & 2.1951e+01 \\
9.6487e+00 & 3.0469e+00 & 3.0469e+00 & 3.0469e+00 \\
1.9999e+00 & 5.3827e+00 & 5.3827e+00 & 5.3827e+00 \\
\end{bmatrix}
\]

\( A(10) = \)

\[
\begin{bmatrix}
2.9845e+00 & 9.6487e+00 & 3.0469e+00 & 3.0469e+00 \\
1.0738e-02 & 2.9849e+00 & 3.6177e+00 & 3.6177e+00 \\
1.5433e-05 & 5.1009e-05 & 5.1009e-05 & 5.1009e-05 \\
\end{bmatrix}
\]

\( A(11) = \)

\[
\begin{bmatrix}
6.8271e-02 & -7.0021e+00 & 2.1931e+01 & 2.1931e+01 \\
9.3652e-01 & 3.0873e+00 & 3.0873e+00 & 3.0873e+00 \\
1.5433e-05 & 5.1009e-05 & 5.1009e-05 & 5.1009e-05 \\
\end{bmatrix}
\]

\( A(12) = \)

\[
\begin{bmatrix}
4.9824e-02 & -7.0308e+00 & 2.1912e+01 & 2.1912e+01 \\
9.3652e-01 & 3.0873e+00 & 3.0873e+00 & 3.0873e+00 \\
-1.7274e-06 & -3.7751e-04 & 1.0014e+00 & 1.0014e+00 \\
\end{bmatrix}
\]

\( A(13) = \)

\[
\begin{bmatrix}
3.9586e-02 & -7.0360e+00 & 2.1908e+01 & 2.1908e+01 \\
9.3652e-01 & 3.0873e+00 & 3.0873e+00 & 3.0873e+00 \\
1.7298e-08 & 5.7677e-07 & 1.0007e+00 & 1.0007e+00 \\
\end{bmatrix}
\]

\( A(14) = \)

\[
\begin{bmatrix}
3.2819e-02 & -7.0388e+00 & 2.1905e+01 & 2.1905e+01 \\
\end{bmatrix}
\]
Looking at the element-wise quotients of the last two matrices one recognizes the convergence rates claimed in (4.2).

\[
A(20)/A(19) = \begin{bmatrix}
1.0000 & 0.9752 & 1.0000 & -1.0000 \\
0.7495 & 1.0000 & 0.9988 & -1.0008 \\
0.5000 & 0.6668 & 1.0000 & -1.0001 \\
-0.2500 & -0.3334 & -0.4999 & 1.0000 \\
\end{bmatrix}
\]

The elements above and on the diagonal are relatively stable.

If we run the same little MATLAB script but with the initial diagonal matrix \(D\) replaced by

\[
D = \text{diag}([5.0 2.0 2.0 1.0]);
\]

then we obtain

\[
A(19) = \begin{bmatrix}
5.0000e+00 & 4.0172e+00 & -9.7427e+00 & -3.3483e+01 \\
-4.2800e-08 & 2.0000e+00 & 2.1100e-05 & -4.3247e+00 \\
1.3027e-08 & 7.0605e-08 & 2.0000e+00 & 2.1769e+00 \\
8.0101e-14 & -2.4420e-08 & 4.8676e-06 & 1.0000e+00 \\
\end{bmatrix}
\]

\[
A(20) = \begin{bmatrix}
5.0000e+00 & 4.0172e+00 & -9.7427e+00 & 3.3483e+01 \\
-1.7120e-08 & 2.0000e+00 & 1.0536e-05 & 4.3247e+00 \\
5.2160e-09 & 3.3588e-08 & 2.0000e+00 & -2.1769e+00 \\
-1.6020e-14 & 1.2210e-08 & -2.4234e-06 & 1.0000e+00 \\
\end{bmatrix}
\]

So, again the eigenvalues are visible on the diagonal of \(A_{20}\). The element-wise quotients of \(A_{20}\) relative to \(A_{19}\) are
4.2. THE HESSENBERG QR ALGORITHM

\[ \frac{A(20)}{A(19)} = \begin{bmatrix} 1.0000 & 1.0000 & 1.0000 & -1.0000 \\ 0.4000 & 1.0000 & 0.4993 & -1.0000 \\ 0.4000 & 0.4753 & 1.0000 & -1.0000 \\ -0.2000 & -0.5000 & -0.5000 & 1.0000 \end{bmatrix} \]

Notice that (4.2) does not state a rate for the element at position (3, 2).

These little numerical tests are intended to demonstrate that the convergence rates given in (4.2) are in fact seen in a real run of the basic QR algorithm. The conclusions we can draw are the following:

1. The convergence of the algorithm is slow. In fact it can be arbitrarily slow if eigenvalues are very close to each other.

2. The algorithm is expensive. Each iteration step requires the computation of the QR factorization of a full \( n \times n \) matrix, i.e., each single iteration step has a complexity \( \mathcal{O}(n^3) \). Even if we assume that the number of steps is proportional to \( n \) we would get an \( \mathcal{O}(n^4) \) complexity. The latter assumption is not even assured, see point 1 of this discussion.

In the following we want to improve on both issues. First we want to find a matrix structure that is preserved by the QR algorithm and that lowers the cost of a single iteration step. Then, we want to improve on the convergence properties of the algorithm.

### 4.2 The Hessenberg QR algorithm

A matrix structure that is close to upper triangular form and that is preserved by the QR algorithm is the Hessenberg form.

**Definition 4.1** A matrix \( H \) is a Hessenberg matrix if its elements below the lower off-diagonal are zero,

\[ h_{ij} = 0, \quad i > j + 1. \]

**Theorem 4.2** The Hessenberg form is preserved by the QR algorithms.

**Proof.** We give a constructive proof, i.e., given a Hessenberg matrix \( H \) with QR factorization \( H = QR \), we show that \( QR = RQ \) is again a Hessenberg matrix.

The **Givens rotation** or **plane rotation** \( G(i, j, \vartheta) \) is defined by

\[
G(i, j, \vartheta) := \begin{bmatrix}
1 & \cdots & 0 & \cdots & 0 & \cdots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \cdots & c & \cdots & s & \cdots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \cdots & -s & \cdots & c & \cdots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \cdots & 0 & \cdots & 0 & \cdots & 1
\end{bmatrix}
\]

where \( c = \cos(\vartheta) \) and \( s = \sin(\vartheta) \). Pre-multiplication by \( G(i, j, \vartheta) \) amounts to a counterclockwise rotation by \( \vartheta \) radians in the \((i,j)\) coordinate plane. Clearly, a Givens rotation is
an orthogonal matrix. For a unitary version see [4]. If \( x \in \mathbb{R}^n \) and \( y = G(i, j, \vartheta)^* x \), then

\[
y_k = \begin{cases} 
  cx_i - sx_j, & k = i \\
  sx_i + cx_j, & k = j \\
  x_k, & k \neq i, j
\end{cases}
\]

We can force \( y_j \) to be zero by setting

\[
(c, s) = \left( \frac{x_i}{\sqrt{|x_i|^2 + |x_j|^2}}, \frac{-x_j}{\sqrt{|x_i|^2 + |x_j|^2}} \right)
\]

Thus, it is a simple matter to zero a single specific entry in a vector by using a Givens rotation\(^1\).

Now, let us look at a Hessenberg matrix \( H \). We can show the principle procedure by means of a \( 4 \times 4 \) example.

\[
H = \begin{bmatrix}
  x & x & x & x \\
  x & x & x & x \\
  0 & x & x & x \\
  0 & 0 & x & x \\
\end{bmatrix}
\]

\[
\xrightarrow{G(1, 2, \vartheta_1)^*} \begin{bmatrix}
  x & x & x & x \\
  0 & x & x & x \\
  0 & 0 & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\]

\[
\xrightarrow{G(2, 3, \vartheta_2)^*} \begin{bmatrix}
  x & x & x & x \\
  0 & x & x & x \\
  0 & 0 & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\]

\[
\xrightarrow{G(3, 4, \vartheta_3)^*} \begin{bmatrix}
  x & x & x & x \\
  0 & x & x & x \\
  0 & 0 & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\]

So, with \( G_k = G(k, k + 1, \vartheta_k) \), we get

\[
\underbrace{G_3 G_2 G_1}_Q H = R \quad \iff \quad H = QR.
\]

Multiplying \( Q \) and \( R \) in reversed order gives

\[
\overline{H} = RQ = RG_1 G_2 G_3,
\]

or, pictorially,

\[
R = \begin{bmatrix}
  x & x & x & x \\
  x & x & x & x \\
  0 & 0 & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\]

\[
\xrightarrow{G(1, 2, \vartheta_1)} \begin{bmatrix}
  x & x & x & x \\
  x & x & x & x \\
  0 & 0 & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\]

\[
\xrightarrow{G(2, 3, \vartheta_2)} \begin{bmatrix}
  x & x & x & x \\
  x & x & x & x \\
  0 & 0 & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\]

\[
\xrightarrow{G(3, 4, \vartheta_3)} \begin{bmatrix}
  x & x & x & x \\
  x & x & x & x \\
  0 & 0 & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\]

More generally, if \( H \) is \( n \times n \), \( n - 1 \) Givens rotations \( G_1, \ldots, G_{n-1} \) are needed to transform \( H \) to upper triangular form. Applying the rotations from the right restores the Hessenberg form. \(
\)

**Remark 4.1.** The Hessenberg nonzero pattern isn’t the only pattern that is preserved by the QR algorithm, see [2], however it is the most simple one. \(\square\)

\(^1\)For a stable way to compute Givens rotations see Algorithm 5.1.3 in [6].
4.2. THE HESSENBERG QR ALGORITHM

4.2.1 A numerical experiment

We repeat one of the previous two MATLAB experiments

\[
\begin{align*}
D &= \text{diag}([4 \ 3 \ 2 \ 1]); \\
\text{rand}'('seed',0); \\
S &= \text{rand}(4); \quad S = (S - .5)*2; \\
A &= S*D*S^{-1} \\
H &= \text{hess}(A); \\
\end{align*}
\]

\[
\begin{align*}
\text{for } i=1:30, \\
\quad [Q,R] &= \text{qr}(H); \\
\quad H &= R*Q \\
\end{align*}
\]

This yields the matrix sequence

\[
\begin{align*}
H(0) &= \begin{bmatrix}
-4.4529e-01 & -1.8641e+00 & -2.8109e+00 & 7.2941e+00 \\
8.0124e+00 & 6.2898e+00 & 1.2058e+11 & -1.6088e+01 \\
0.0000e+00 & 4.0087e-01 & -1.5744e-01 & 3.0010e+00 \\
0.0000e+00 & 0.0000e+00 & -1.5744e-01 & 3.0010e+00 \\
\end{bmatrix} \\
H(5) &= \begin{bmatrix}
4.0763e+00 & -2.7930e+00 & -7.1102e+00 & 2.1826e+01 \\
5.6860e-02 & 2.4389e+00 & -1.2553e+00 & -3.5061e+00 \\
-2.0209e-01 & 2.5681e+00 & -1.2058e+11 & -1.6088e+01 \\
4.3525e-02 & 9.1667e-01 & 3.3549e+00 & 3.0010e+00 \\
\end{bmatrix} \\
H(10) &= \begin{bmatrix}
4.0024e+00 & -6.2734e-01 & -7.0411e+00 & 2.1902e+01 \\
7.6515e-03 & 2.9123e+00 & -9.9902e-01 & 3.3560e+00 \\
-8.0039e-02 & 2.0877e+00 & 3.3549e+00 & 3.0010e+00 \\
-7.1186e-04 & 9.9762e-01 & 3.0010e+00 & 3.0010e+00 \\
\end{bmatrix} \\
H(15) &= \begin{bmatrix}
4.0001e+00 & -1.0549e-01 & -7.0411e+00 & 2.1902e+01 \\
1.6833e-03 & 2.9889e+00 & -8.9365e-01 & 3.6032e+00 \\
-1.2248e-02 & 2.0111e+00 & 3.6377e+00 & 3.0010e+00 \\
2.0578e-05 & 9.9993e-01 & 3.0010e+00 & 3.0010e+00 \\
\end{bmatrix} \\
H(20) &= \begin{bmatrix}
4.0000e+00 & -3.1163e-02 & -7.0425e+00 & -2.1898e+01 \\
3.9562e-04 & 2.9986e+00 & -8.7411e-01 & 3.2072e+00 \\
-1.6441e-03 & 2.0014e+00 & 3.6377e+00 & 3.0010e+00 \\
-6.3689e-07 & 1.0000e-00 & 3.0010e+00 & 3.0010e+00 \\
\end{bmatrix} \\
H(25) &= \begin{bmatrix}
4.0000e+00 & -2.1399e-02 & -7.0428e+00 & 2.1897e+01 \\
9.3764e-05 & 2.9986e+00 & -8.7056e-01 & -3.2086e+00 \\
-2.1704e-04 & 2.0002e+00 & 3.6423e+00 & 3.0010e+00 \\
1.9878e-08 & 1.0000e-00 & 3.0010e+00 & 3.0010e+00 \\
\end{bmatrix} \\
H(30) &= \begin{bmatrix}
4.0000e+00 & -2.0143e-02 & -7.0429e+00 & -2.1897e+01 \\
2.2247e-05 & 3.0000e+00 & -8.6987e-01 & 3.2095e+00 \\
-2.8591e-05 & 2.0000e+00 & 3.6429e+00 & 3.0010e+00 \\
-6.2168e-10 & 1.0000e-00 & 3.0010e+00 & 3.0010e+00 \\
\end{bmatrix}
\]

Finally we compute the element-wise quotients of the last two matrices.

\[
\begin{align*}
H(30)/H(29) &= \begin{bmatrix}
1.0000 & 0.9954 & 1.0000 & -1.0000 \\
0.7500 & 1.0000 & 0.9999 & -1.0000 \\
0.6667 & 1.0000 & -1.0000 \\
-0.5000 & 1.0000 \\
\end{bmatrix}
\end{align*}
\]

Again the elements in the lower off-diagonal reflect nicely the convergence rates in (4.2).
4.2.2 Complexity

We give the algorithm for a single Hessenberg-QR-step in a MATLAB-like way, see Algorithm 4.2. By

\[ H_{k:j,m:n} \]

we denote the submatrix of \( H \) consisting of rows \( k \) through \( j \) and columns \( m \) through \( n \).

**Algorithm 4.2 A Hessenberg QR step**

1: Let \( H \in \mathbb{C}^{n \times n} \) be an upper Hessenberg matrix. This algorithm overwrites \( H \) with \( H = RQ \) where \( H = QR \) is a QR factorization of \( H \).
2: for \( k = 1, 2, \ldots, n - 1 \) do
3:   /* Generate \( G_k \) and then apply it: \( H = G(k, k+1, 0_k)H */
4:   \([c_k, s_k] := \text{givens}(H_{k,k}, H_{k+1,k});\)
5:   \[H_{k:k+1,k:n} := \begin{bmatrix} c_k & -s_k \\ s_k & c_k \end{bmatrix} H_{k:k+1,k:n};\]
6:   end for
7: for \( k = 1, 2, \ldots, n - 1 \) do
8:   /* Apply the rotations \( G_k \) from the right */
9:   \[H_{1:1,k+1,k+1} = H_{1:1,k+1,k+1} \begin{bmatrix} c_k & s_k \\ -s_k & c_k \end{bmatrix};\]
10: end for

If we neglect the determination of the parameters \( c_k \) and \( s_k \), see (4.5), then each of the two loops requires

\[ \sum_{i=1}^{n-1} 6i = 6 \frac{n(n - 1)}{2} \approx 3n^2 \] flops.

A **flop** is a floating point operation (+, -, \( \times \), \( \div \)). We do not distinguish between them, although they may slightly differ in their execution time on a computer. Optionally, we also have to execute the operation \( U_k := U_{k-1}Q_k \) of Algorithm 4.1. This is achieved by a loop similar to the second loop in Algorithm 4.2. Since all the rows and columns of \( U \) are involved, executing the loop costs

\[ \sum_{i=1}^{n-1} 6n \approx 6n^2 \] flops.

Altogether, a QR step with a Hessenberg matrix, including the update of the unitary transformation matrix, requires \( 12n^2 \) floating point operations. This has to be set in relation to a QR step with a full matrix that costs \( \frac{2}{3}n^3 \). Consequently, we have gained a factor of \( O(n) \) in terms of operations by moving from dense to Hessenberg form. However, we may still have very slow convergence if one of the quotients \( |\lambda_k|/|\lambda_{k+1}| \) is close to 1.
4.3. THE HOUSEHOLDER REDUCTION TO HESSENBerg FORM

4.3 The Householder reduction to Hessenberg form

In the previous section we discovered that it is a good idea to perform the QR algorithm with Hessenberg matrices instead of full matrices. But we have not discussed how we transform a full matrix (by means of similarity transformations) into Hessenberg form. We catch up on this issue in this section.

4.3.1 Householder reflectors

Givens rotations are designed to zero a single element in a vector. Householder reflectors are more efficient if a number of elements of a vector are to be zeroed at once. Here, we follow the presentation given in [6].

Definition 4.3 A matrix of the form
\[ P = I - 2uu^*, \quad ||u|| = 1, \]
is called a Householder reflector.

It is easy to verify that Householder reflectors are Hermitian and that \( P^2 = I \). From this we deduce that \( P \) is unitary. It is clear that we only have to store the Householder vector \( u \) to be able to multiply a vector (or a matrix) with \( P \),
\[(4.6) \quad Px = x - u(2u^*x).\]

This multiplication only costs \( 4n \) flops where \( n \) is the length of the vectors.

A task that we repeatedly want to carry out with Householder reflectors is to transform a vector \( x \) on a multiple of \( e_1 \),
\[ Px = x - u(2u^*x) = \alpha e_1. \]

Since \( P \) is unitary, we must have \( \alpha = \rho ||x|| \), where \( \rho \in \mathbb{C} \) has absolute value one. Therefore,
\[ u = \frac{x - \rho ||x|| e_1}{||x - \rho ||x|| e_1||} = \frac{1}{||x - \rho ||x|| e_1||} \begin{bmatrix} x_1 - \rho ||x|| \\ x_2 \\ \vdots \\ x_n \end{bmatrix} \]

We can freely choose \( \rho \) provided that \( |\rho| = 1 \). Let \( x_1 = |x_1|e^{i\phi} \). To avoid numerical cancellation we set \( \rho = -e^{i\phi} \).

In the real case, one commonly sets \( \rho = -\text{sign}(x_1) \). If \( x_1 = 0 \) we can set \( \rho \) in any way.

4.3.2 Reduction to Hessenberg form

Now we show how to use Householder reflectors to reduce an arbitrary square matrix to Hessenberg form. We show the idea by means of a 5 \times 5 example. In the first step of the reduction we introduce zeros in the first column below the second element,
\[ A = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \end{bmatrix} \xrightarrow{P_1} \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \xrightarrow{*P_1} \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} = P_1^* A P_1. \]
CHAPTER 4. THE QR ALGORITHM

Notice that \( P_1 = P_1^* \) since it is a Householder reflector! It has the structure

\[
P_1 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & x & x & x \\ 0 & x & x & x \\ 0 & x & x & x \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & I_4 - 2u_1u_1^* \end{bmatrix}.
\]

The Householder vector \( u_1 \) is determined such that

\[
(I - 2u_1u_1^*) \begin{bmatrix} a_{21} \\ a_{31} \\ a_{41} \\ a_{51} \end{bmatrix} = \begin{bmatrix} \alpha \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad \text{with} \quad u_1 = \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{bmatrix}.
\]

The multiplication of \( P_1 \) from the left inserts the desired zeros in column 1 of \( A \). The multiplication from the right is necessary in order to have similarity. Because of the nonzero structure of \( P_1 \) the first column of \( P_1A \) is not affected. Hence, the zeros stay there.

The reduction continues in a similar way:

\[
P_1AP_1 = \begin{bmatrix} x & x & x & x \\ x & x & x & x \\ 0 & x & x & x \\ 0 & x & x & x \end{bmatrix} \quad \text{\( P_2 \) from the left:} \quad \begin{bmatrix} x & x & x & x \\ x & x & x & x \\ 0 & 0 & x & x \\ 0 & 0 & 0 & x \end{bmatrix}
\]

\[
P_3 \quad \text{\( P_3 \) from the right:} \quad \begin{bmatrix} x & x & x & x \\ x & x & x & x \\ 0 & 0 & x & x \\ 0 & 0 & 0 & x \end{bmatrix}
\]

Algorithm 4.3 gives the details for the general \( n \times n \) case. In step 4 of this algorithm, the Householder reflector is generated such that

\[
(I - 2u_ku_k^*) \begin{bmatrix} a_{k+1,k} \\ a_{k+2,k} \\ \vdots \\ a_{n,k} \end{bmatrix} = \begin{bmatrix} \alpha \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad \text{with} \quad u_k = \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_{n-k} \end{bmatrix} \quad \text{and} \quad |\alpha| = ||x||
\]

according to the considerations of the previous subsection. The Householder vectors are stored at the locations of the zeros. Therefore the matrix \( U = P_1 \cdots P_{n-2} \) that effects the similarity transformation from the full \( A \) to the Hessenberg \( H \) is computed after all Householder vectors have been generated, thus saving \((2/3)n^3\) flops. The overall complexity of the reduction is

- Application of \( P_k \) from the left: \( \sum_{k=1}^{n-2} 4(n-k)(n-k) \approx \frac{4}{3}n^3 \)
- Application of \( P_k \) from the right: \( \sum_{k=1}^{n-2} 4(n)(n-k) \approx 2n^3 \)
4.4. IMPROVING THE CONVERGENCE OF THE QR ALGORITHM

Algorithm 4.3 Reduction to Hessenberg form

1. This algorithm reduces a matrix $A \in \mathbb{C}^{n \times n}$ to Hessenberg form $H$ by a sequence of Householder reflections. $H$ overwrites $A$.
2. for $k = 1$ to $n-2$ do
3. Generate the Householder reflector $P_k$;
4. /* Apply $P_k = I_k \oplus (I_{n-k} - 2u_k u_k^*)$ from the left to $A^*$ /
5. $A_{k+1:n;k:n} := A_{k+1:n;k:n} - 2u_k u_k^* A_{k+1:n;k:n}$;
6. /* Apply $P_k$ from the right, $A := A P_k^*$ /
7. $A_{1:n,k+1:n} := A_{1:n,k+1:n} - 2(A_{1:n,k+1:n} u_k) u_k^*$;
8. end for
9. if eigenvectors are desired form $U = P_1 \cdots P_{n-2}$ then
10. $U := I_n$;
11. for $k = n-2$ downto 1 do
12. /* Update $U := P_k U$ */
13. $U_{k+1:n,k+1:n} := U_{k+1:n,k+1:n} - 2u_k u_k^* U_{k+1:n,k+1:n}$;
14. end for
15. end if

- Form $U = P_1 \cdots P_{n-2}: \sum_{k=1}^{n-2} 4(n-k)(n-k) \approx \frac{4}{3} n^3$

Thus, the reduction to Hessenberg form costs $\frac{10}{3} n^3$ flops without forming the transformation matrix and $\frac{14}{3} n^3$ including forming this matrix.

4.4 Improving the convergence of the QR algorithm

We have seen how the QR algorithm for computing the Schur form of a matrix $A$ can be executed more economically if the matrix $A$ is first transformed to Hessenberg form. Now we want to show how the convergence of the Hessenberg QR algorithm can be improved dramatically by introducing (spectral) shifts into the algorithm.

Lemma 4.4 Let $H$ be an irreducible Hessenberg matrix, i.e., $h_{i+1,i} \neq 0$ for all $i = 1, \ldots, n-1$. Let $H = QR$ be the QR factorization of $H$. Then for the diagonal elements of $R$ we have

$$|r_{kk}| > 0,$$

for all $k < n$.

Thus, if $H$ is singular then $r_{nn} = 0$.

Proof. Let us look at the $k$-th step of the Hessenberg QR factorization. For illustration, let us consider the case $k = 3$ in a $5 \times 5$ example, where the matrix has the structure

$$\begin{bmatrix}
+ & + & + & + \\
0 & + & + & + \\
0 & 0 & + & + \\
0 & 0 & \times & \times \\
0 & 0 & 0 & \times
\end{bmatrix}$$

The plus-signs indicate elements that have been modified. In step 3, the (nonzero) element $h_{43}$ will be zeroed by a Givens rotation $G(3, 4, \varphi)$ that is determined such that

$$\begin{bmatrix}
\cos(\varphi) & -\sin(\varphi) \\
\sin(\varphi) & \cos(\varphi)
\end{bmatrix}
\begin{bmatrix}
\tilde{h}_{kk} \\
h_{k+1,k}
\end{bmatrix} =
\begin{bmatrix}
r_{kk} \\
0
\end{bmatrix}.$$
Because the Givens rotation preserves vector lengths, we have
\[ |r_{kk}|^2 = |\tilde{h}_{kk}|^2 + |h_{k+1,k}|^2 \geq |h_{k+1,k}|^2 > 0, \]
which confirms the claim.

We apply this Lemma to motivate a further strategy to speed up the convergence of the QR algorithm.

Let \( \lambda \) be an eigenvalue of the irreducible Hessenberg matrix \( H \). Let us check what happens if we perform

1: \( H - \lambda I = QR \) /* QR factorization */
2: \( \overline{H} = RQ + \lambda I \)

First we notice that \( \overline{H} \sim H \). In fact,
\[ H = Q^* (H - \lambda I) Q + \lambda I = Q^* H Q. \]
Second, by Lemma 4.4 we have
\[ H - \lambda I = QR, \quad \text{with} \quad R = \begin{bmatrix} \phantom{0} \\ 0 \end{bmatrix}. \]
Thus,
\[ RQ = \begin{bmatrix} \phantom{0} \\ 0 \end{bmatrix} \]
and
\[ \overline{H} = RQ + \lambda I = \begin{bmatrix} \phantom{0} \\ 0 \lambda \end{bmatrix} = \begin{bmatrix} H_1 & h_1 \\ 0^T & \lambda \end{bmatrix}. \]
So, if we apply a QR step with a **perfect shift** to a Hessenberg matrix, the eigenvalue drops out. We then could **deflate**, i.e., proceed the algorithm with the smaller matrix \( H_1 \).

**Remark 4.2.** We could prove the existence of the Schur decomposition in the following way. (1) transform the arbitrary matrix to Hessenberg form. (2) Do the perfect shift Hessenberg QR with the eigenvalues which we known to exist one after the other. □

### 4.4.1 A numerical example

We use a matrix of a previous MATLAB experiments to show that perfect shifts actually work.

```matlab
D = diag([4 3 2 1]); rand('seed',0);
S=rand(4); S = (S -.5)*2;
A = S*D/S;
format short e
H = hess(A)
[Q,R] = qr(H - 2*eye(4))
H1 = R*Q + 2*eye(4)
format long
lam = eig(H1(1:3,1:3))
```
MATLAB produces the output

\[
H = \begin{bmatrix}
-4.4529e-01 & -1.8641e+00 & -2.8109e+00 & 7.2941e+00 \\
8.0124e+00 & 6.2898e+00 & 1.2058e+11 & -1.6088e+01 \\
4.0087e-01 & 1.1545e+00 & -3.3722e-01 & 7.2941e+00 \\
-1.5744e-01 & 3.0010e+00 & 8.0124e+00 & 6.2898e+00 \\
\end{bmatrix}
\]

\[
Q = \begin{bmatrix}
9.5645e-01 & -2.3292e-01 & -1.3039e-01 & -1.1810e-01 \\
6.0270e-01 & -5.9144e-01 & -5.3568e-01 & -5.3568e-01 \\
-6.7130e-01 & 7.3772e+00 & 4.6471e+00 & 1.2353e+11 \\
\end{bmatrix}
\]

\[
R = \begin{bmatrix}
8.3772e+00 & 4.6471e+00 & 1.2353e+11 & -1.7517e+01 \\
6.6513e-01 & -1.1728e+00 & -2.0228e+00 & 2.3453e-01 \\
2.3453e-01 & -1.4912e+00 & 2.3453e-01 & -2.4425e-14 \\
-2.4425e-14 & 2.0000e+00 & 2.0000e+00 & 2.0000e+00 \\
\end{bmatrix}
\]

\[
H_1 = \begin{bmatrix}
3.9994e+00 & -3.0986e-02 & 2.6789e-01 & -2.3391e+11 \\
6.3616e-01 & 1.1382e+00 & 1.9648e+00 & -9.4962e-01 \\
1.4135e-01 & 2.8623e+00 & -1.2309e+00 & 1.6396e-14 \\
1.6396e-14 & 2.0000e+00 & 2.0000e+00 & 2.0000e+00 \\
\end{bmatrix}
\]

\[
\lambda = [9.99999999999993e-01 4.00000000000003e+00 3.00000000000000e+00]
\]

4.4.2 QR algorithm with shifts

This considerations indicate that it may be good to introduce shifts into the QR algorithm. However, we cannot choose perfect shifts because we do not know the eigenvalues of the matrix! We therefore need heuristics how to estimate eigenvalues. One such heuristic is the Rayleigh quotient shift: Set the shift \( \sigma_k \) in the \( k \)-th step of the QR algorithm equal to the last diagonal element:

\[
(4.7) \quad \sigma_k := h_{n,n}^{(k-1)} = e_n^* H^{(k-1)} e_n.
\]

Algorithm 4.4 The Hessenberg QR algorithm with Rayleigh quotient shift

1. Let \( H_0 = H \in \mathbb{C}^{n \times n} \) be an upper Hessenberg matrix. This algorithm computes its Schur normal form \( H = U T U^* \).
2. \( k := 0 \);
3. for \( m=n,n-1,\ldots,2 \) do
4. \hspace{1em} repeat
5. \hspace{2em} \( k := k + 1 \);
6. \hspace{2em} \( \sigma_k := h_{m,m} \);
7. \hspace{2em} \( H_{k-1} - \sigma_k I := Q_k R_k \);
8. \hspace{2em} \( H_k := R_k Q_k + \sigma_k I \);
9. \hspace{2em} \( U_k := U_{k-1} Q_k \);
10. until \( |h_{m,m-1}^{(k)}| \) is sufficiently small
11. end for
12. \( T := H_k \);

Algorithm 4.4 implements this heuristic. Notice that the shift changes in each iteration step! Notice also that deflation is incorporated in Algorithm 4.4. As soon as the last lower off-diagonal element is sufficiently small, it is declared zero, and the algorithm proceeds with a smaller matrix. In Algorithm 4.4 the ‘active portion’ of the matrix is \( m \times m \).
Lemma 4.4 guarantees that a zero is produced at position \((n, n-1)\) in the Hessenberg matrix \(H\) if the shift equals an eigenvalue of \(H\). What happens, if \(h_{n,n}\) is a good approximation to an eigenvalue of \(H\)? Let us assume that we have an irreducible Hessenberg matrix

\[
\begin{bmatrix}
\times & \times & \times & \times \\
\times & \times & \times & \times \\
0 & \times & \times & \times \\
0 & 0 & \times & \times \\
0 & 0 & 0 & \varepsilon & h_{n,n}
\end{bmatrix},
\]

where \(\varepsilon\) is a small quantity. If we perform a shifted Hessenberg QR step, we first have to factor \(H - h_{n,n}I\), \(QR = H - h_{n,n}I\). After \(n-2\) steps of this factorization the \(R\)-factor is almost upper triangular,

\[
\begin{bmatrix}
+ & + & + & + \\
0 & + & + & + \\
0 & 0 & + & + \\
0 & 0 & 0 & \alpha & \beta \\
0 & 0 & 0 & \varepsilon & 0
\end{bmatrix}.
\]

From (4.5) we see that the last Givens rotation has the nontrivial elements

\[
c_{n-1} = \frac{\alpha}{\sqrt{|\alpha|^2 + |\varepsilon|^2}} \quad s_{n-1} = \frac{-\varepsilon}{\sqrt{|\alpha|^2 + |\varepsilon|^2}}.
\]

Applying the Givens rotations from the right one sees that the last lower off-diagonal element of \(RH = RQ + h_{n,n}I\) becomes

\[
(4.8) \quad \bar{h}_{n,n-1} = \frac{\varepsilon^2 \beta}{\alpha^2 + \varepsilon^2}.
\]

So, we have quadratic convergence unless \(\alpha\) is also tiny.

A second even more often used shift strategy is the Wilkinson shift:

\[
(4.9) \quad \sigma_k := \text{eigenvalue of } \begin{bmatrix} h_{n-1,n-1}^{(k-1)} & h_{n-1,n}^{(k-1)} \\ h_{n,n-1}^{(k-1)} & h_{n,n}^{(k-1)} \end{bmatrix} \text{ that is closer to } h_{n,n}^{(k-1)}.
\]

### 4.4.3 A numerical example

We give an example for the Hessenberg QR algorithm with shift, but without deflation. The MATLAB code

```matlab
D = diag([4 3 2 1]);
rand(‘seed’,0);
S=rand(4); S = (S -.5)*2;
A = S*D/S;
H = hess(A);

for i=1:8,
    [Q,R] = qr(H-H(4,4)*eye(4)); H = R*Q+H(4,4)*eye(4);
end
```

produces the output
4.5. THE DOUBLE SHIFT QR ALGORITHM

\[
H(0) = \begin{bmatrix}
-4.4529e-01 & -1.8641e+00 & -2.8109e+00 & 7.2941e+00 \\

-1.5891e-01 & 2.3123e+00 & -1.1140e-01 & 3.0000e+00 \\
-1.0026e-119 & 2.9998e+00 & 3.0010e+00 & 3.0000e+00
\end{bmatrix}
\]

\[
H(7) = \begin{bmatrix}
9.7303e-01 & -6.4754e-01 & -8.9829e-03 & -1.8034e+00 \\
8.2551e-02 & 2.3138e+00 & 3.9755e+00 & -3.8885e+00 \\
3.3599e-02 & 2.5418e+00 & -7.0915e-02 & 3.0000e+00 \\
3.3770e-239 & 3.0000e+00 & 3.0000e+00 & 3.0000e+00
\end{bmatrix}
\]

\[
H(8) = \begin{bmatrix}
1.0002e+00 & -8.1614e-01 & -8.9331e-01 & 1.9636e+00 \\
-1.8704e-02 & 2.9998e+00 & 3.0000e+00 & 3.0000e+00 \\
-1.5660e-01 & 2.9998e+00 & 3.0010e+00 & 3.0000e+00 \\
0 & 3.0000e+00 & 3.0000e+00 & 3.0000e+00
\end{bmatrix}
\]

The numerical example shows that the shifted Hessenberg QR algorithm can work very nicely. In this example the (4,3) element is about $10^{-30}$ after 3 steps. (We could stop there.) The example also nicely shows a quadratic convergence rate.

4.5 The double shift QR algorithm

The shifted Hessenberg QR algorithm does not always work so nicely as in the previous example. If $\alpha$ in (4.8) is $O(\varepsilon)$ then $h_{n,n-1}$ can be large. (A small $\alpha$ indicates a near singular $H_{1:n-1,n-1}$.)

Another problem occurs if real Hessenberg matrices have complex eigenvalues. We know that for reasonable convergence rates the shifts must be complex. If an eigenvalue $\lambda$ has been found we can execute a single perfect shift with $\bar{\lambda}$. It is (for rounding errors) improbable however that we will get back to a real matrix.
Since the eigenvalues come in complex conjugate pairs it is natural to search for a pair of eigenvalues right-away. This is done by collapsing two shifted QR steps in one double step with the two shifts being complex conjugates of each other.

Let \( \sigma_1 \) and \( \sigma_2 \) be two eigenvalues of the real matrix (cf. Wilkinson shift \((4.9)\))

\[
G = \begin{bmatrix} h_{n-1,n-1}^{(k-1)} & h_{n-1,n}^{(k-1)} \\ h_{n,n-1}^{(k-1)} & h_{n,n}^{(k-1)} \end{bmatrix} \in \mathbb{R}^{2 \times 2}.
\]

If \( \sigma_1 \in \mathbb{C} \setminus \mathbb{R} \) then \( \sigma_2 = \overline{\sigma_1} \). Let us perform two QR steps using \( \sigma_1 \) and \( \sigma_2 \) as shifts. Setting \( k = 1 \) for convenience we get

\[
\begin{align*}
H_0 - \sigma_1 I &= Q_1 R_1, \\
H_1 &= R_1 Q_1 + \sigma_1 I, \\
H_1 - \sigma_2 I &= Q_2 R_2, \\
H_2 &= R_2 Q_2 + \sigma_2 I.
\end{align*}
\]

From the second and third equation in \((4.10)\) we obtain

\[
R_1 Q_1 + (\sigma_1 - \sigma_2) I = Q_2 R_2.
\]

Multiplying this equation with \( Q_1 \) from the left and with \( R_1 \) from the right we get

\[
Q_1 R_1 Q_1 R_1 + (\sigma_1 - \sigma_2) Q_1 R_1 = Q_1 R_1 (Q_1 R_1 + (\sigma_1 - \sigma_2) I) = (H_0 - \sigma_1 I)(H_0 - \sigma_2 I) = Q_1 Q_2 R_2 R_1.
\]

Because \( \sigma_2 = \overline{\sigma_1} \) we have

\[
M := (H_0 - \sigma_1 I)(H_0 - \overline{\sigma_1} I) = H_0^2 - 2 \text{Re}(\sigma) H_0 + |\sigma|^2 I = Q_1 Q_2 R_2 R_1.
\]

Therefore, \((Q_1 Q_2)(R_2 R_1)\) is the QR factorization of a real matrix. We can choose (scale) \( Q_1 \) and \( Q_2 \) such that \( Z := Q_1 Q_2 \) is real orthogonal. (Then also \( R_2 R_1 \) is real.) By consequence,

\[
H_2 = (Q_1 Q_2)^* H_0 (Q_1 Q_2) = Z^T H_0 Z
\]

is real.

A procedure to compute \( H_2 \) by avoiding complex arithmetic could consist of three steps:

1. Form the real matrix \( M = H_0^2 - s H_0 + t I \) with \( s = 2 \text{Re}(\sigma) = \text{trace}(G) = h_{n-1,n-1}^{(k-1)} + h_{n,n}^{(k-1)} \) and \( t = |\sigma|^2 = \text{det}(G) = h_{n-1,n-1}^{(k-1)} h_{n,n}^{(k-1)} - h_{n-1,n}^{(k-1)} h_{n,n-1}^{(k-1)} \). Notice that \( M \) has two lower off-diagonals,

\[
M = \begin{bmatrix} & \hline & \\
\end{bmatrix}.
\]

2. Compute the QR factorization \( M = Z R \),

3. Set \( H_2 = Z^T H_0 Z \).

This procedure is however too expensive since item 1, i.e., forming \( H^2 \) requires \( \mathcal{O}(n^3) \) flops.

A remedy for the situation is provided by the Implicit Q Theorem.
4.5. THE DOUBLE SHIFT QR ALGORITHM

Theorem 4.5 (The implicit Q theorem) Let $A \in \mathbb{R}^{n \times n}$. Let $Q = [q_1, \ldots, q_n]$ and $V = [v_1, \ldots, v_n]$ be orthogonal matrices that both similarly transform $A$ to Hessenberg form, $H = Q^T AQ$ and $G = V^T AV$. Let $k$ denote the smallest positive integer for which $h_{k+1,k} = 0$, with $k = n$ if $H$ is irreducible.

If $q_1 = v_1$ then $q_i = \pm v_i$ and $|h_{i,i-1}| = |g_{i,i-1}|$ for $i = 2, \ldots, k$. If $k < n$, then $g_{k+1,k} = 0$.

We first show that the first $k$ columns of $W$ form an upper triangular matrix, i.e.,

\begin{equation}
(4.11) \quad w_i = We_i \in \text{span}\{e_1, \ldots, e_i\}, \quad i \leq k.
\end{equation}

(Notice that orthogonal upper triangular matrices are diagonal with diagonal entries $\pm 1$.)

This is proved inductively. For $i = 1$ we have $w_1 = e_1$ by the assumption that $q_1 = v_1$. For $1 < i \leq k$ we assume that (4.11) is true for $w_i$ and use the equality $GW = WH$. The $(i-1)$-th column of this equation reads

$$Gw_{i-1} = GW e_{i-1} = WH e_{i-1} = \sum_{j=1}^{i-1} w_j h_{j,i-1}.$$ 

Since $h_{i,i-1} \neq 0$ we have

$$w_i h_{i,i-1} = Gw_{i-1} - \sum_{j=1}^{i-1} w_j h_{j,i-1} \in \text{span}\{e_1, \ldots, e_i\},$$

as $G$ is a Hessenberg matrix. So, the upper-left $k \times k$ block of $W$ is upper triangular. Since the columns of $W$ are orthogonal we conclude that $w_i = \pm e_i$, $i \leq k$.

Since $w_i = \pm V^T Q e_i = V^T q_i = \pm e_i$ we see that $q_i$ is orthogonal to all columns of $V$ except the $i$-th. Therefore, we must have $q_i = \pm v_i$. Further,

$$h_{i,i-1} = e_i^T He_{i-1} = e_i^T Q^T A Q e_{i-1} = e_i^T Q^T V G V^T Q e_{i-1} = w_i^T G w_{i-1} = \pm g_{i,i-1},$$

thus, $|h_{i,i-1}| = |g_{i,i-1}|$. If $h_{k+1,k} = 0$ then

$$g_{k+1,k} = e_{k+1}^T G e_k = \pm e_{k+1}^T G W e_k = \pm e_{k+1}^T W H e_k = \pm e_{k+1}^T \sum_{j=1}^{k} w_j h_{j,k} = 0,$$

since $e_{k+1}^T w_j = \pm e_{k+1}^T e_j = 0$ for $j \leq k$. \hfill \rule{2mm}{2mm}

Golub and van Loan [6, p.347] write that “The gist of the implicit Q theorem is that if $Q^T AQ = H$ and $Z^T AZ = G$ are both unreduced Hessenberg matrices and $Q$ and $Z$ have the same first column, then $G$ and $H$ are “essentially equal” in the sense that $G = DHD$ with $D = \text{diag}(\pm 1, \ldots, \pm 1)$.”

We apply the Implicit Q Theorem in the following way: We want to compute the Hessenberg matrix $H_{k+1} = Z^T H_{k-1} Z$ where $ZR$ is the QR factorization of $M = H_{k-1}^2 - sh_{k-1} + tf$. The Implicit Q Theorem now tells us that we essentially get $H_{k+1}$ by an orthogonal similarity transformation $H_{k-1} \rightarrow Z_1^* H_{k-1} Z_1$ provided that $Z_1^* H Z_1$ is Hessenberg and $Z_1 e_1 = Z e_1.$
Let $P_0$ be the Householder reflector with

$$P_0^T M e_1 = P_0^T (H_{k-1}^2 - 2\text{Re}(\sigma)H_{k-1} + |\sigma|^2 I) e_1 = \alpha e_1.$$ 

Since only the first three elements of the first column $M e_1$ of $M$ are nonzero, $P_0$ has the structure

$$P_0 = \begin{bmatrix}
\times & \times & \times \\
\times & \times & \times \\
\times & \times & \times \\
1 & \ddots & \\
& & 1
\end{bmatrix}.$$ 

So,

$$H'_{k-1} := P_0^T H_{k-1} P_0 = \begin{bmatrix}
\times & \times & \times & \times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times & \times & \times & \times \\
+ & + & X & X & X & X & X & X & X \\
+ & + & + & X & X & X & X & X & X \\
+ & + & + & + & X & X & X & X & X \\
+ & + & + & + & + & X & X & X & X \\
+ & + & + & + & + & + & X & X & X \\
+ & + & + & + & + & + & + & X & X \\
+ & + & + & + & + & + & + & + & X
\end{bmatrix}.$$ 

We now reduce $P_0^T H_{k-1} P_0$ similarly to Hessenberg form the same way as we did earlier, by a sequence of Householder reflectors $P_1, \ldots, P_{n-2}$. However, $P_0^T H_{k-1} P_0$ is a Hessenberg matrix up to the bulge at the top left. We take into account this structure when forming the $P_i = I - 2p_i p_i^T$. So, the structures of $P_1$ and of $P_1^T P_0^T H_{k-1} P_0 P_1$ are

$$P_1 = \begin{bmatrix}
1 & & & & \\
\times & \times & \times & & \\
\times & \times & \times & & \\
\times & \times & \times & \times & \\
1 & & & & 1
\end{bmatrix}, \quad H''_{k-1} = P_1^T H'_{k-1} P_1 = \begin{bmatrix}
\times & \times & \times & \times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times & \times & \times & \times \\
0 & + & + & X & X & X & X & X & X \\
0 & + & + & X & X & X & X & X & X \\
0 & + & + & X & X & X & X & X & X
\end{bmatrix}.$$ 

The transformation with $P_1$ has chased the bulge one position down the diagonal. The consecutive reflectors push it further by one position each until it falls out of the matrix at the end of the diagonal. Pictorially, we have

$$H'''_{k-1} = P_2^T H''_{k-1} P_2 = \begin{bmatrix}
\times & \times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times & \times \\
0 & + & + & X & X & X & X \\
0 & + & + & X & X & X & X \\
0 & + & + & X & X & X & X
\end{bmatrix} \quad H'''_{k-1} = P_3^T H'''_{k-1} P_3 = \begin{bmatrix}
\times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times \\
0 & + & + & X & X & X \\
0 & + & + & X & X & X \\
0 & + & + & X & X & X
\end{bmatrix}.$$
4.5. THE DOUBLE SHIFT QR ALGORITHM

$$H_{k-1}^{mn} = P_4^T H_{k-1}^{mn} P_4 = \begin{bmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ 0 & x & x & x & 0 \end{bmatrix}$$

$$H_{k-1}^{mn} = P_5^T H_{k-1}^{mn} P_5 = \begin{bmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ 0 & x & x & x & 0 \end{bmatrix}$$

It is easy to see that the Householder vector $p_i$, $i < n-2$, has only three nonzero elements at position $i + 1, i + 2, i + 3$. Of $p_{n-2}$ only the last two elements are nonzero. Clearly, $P_0 P_1 \cdots P_{n-2} e_1 = P_0 e_1 = M e_1 / \alpha$.

**Remark 4.3.** Notice that in Algorithm 4.5 a double step is taken also if the eigenvalues of $G = \begin{bmatrix} h_{qq} & h_{qp} \\ h_{pq} & h_{pp} \end{bmatrix}$ are real. As in the complex case we set $s = \text{trace}(G)$ and $t = \text{det}(G)$. □

### 4.5.1 A numerical example

We consider a simple MATLAB implementation of the Algorithm 4.5 to compute the eigenvalues of the real matrix

$$A = \begin{bmatrix} 7 & 3 & 4 & -11 & -9 & -2 \\ -6 & 4 & -5 & 7 & 1 & 12 \\ -1 & -9 & 2 & 2 & 9 & 1 \\ -8 & 0 & -1 & 5 & 0 & 8 \\ -4 & 3 & -5 & 7 & 2 & 10 \\ 6 & 1 & 4 & -11 & -7 & -1 \end{bmatrix}$$

that has the spectrum

$$\sigma(A) = \{1 \pm 2i, 3, 4, 5 \pm 6i\}.$$ 

The intermediate output of the code was (after some editing) the following:

```
>> H=hess(A)
H(0) =

7.0000    7.2761    5.8120   -0.1397    9.0152    7.9363
12.3693    4.1307   18.9685   -1.2071   10.6833   2.4160
 0   -7.1603    2.4478   -0.5656   -4.1814    5.7230

Algorithm 4.5 The Francis double step QR algorithm

1: Let $H_0 = H \in \mathbb{R}^{n \times n}$ be an upper Hessenberg matrix. This algorithm computes its
real Schur form $H = UTU^T$ using the Francis double step QR algorithm. $T$ is a quasi
upper triangular matrix.

2: $p := n$; /* $p$ indicates the ‘active’ matrix size. */

3: while $p > 2$ do

4: $q := p - 1$;

5: $s := H_{q,q} + H_{p,p}$; $t := H_{q,p}H_{p,q} - H_{q,q}H_{p,p}$;

6: /* compute first 3 elements of first column of $M$ */

7: $x := H_{2,1}^2 + H_{1,2}H_{2,1} - sH_{1,1} + t$;

8: $y := H_{2,1}(H_{1,1} + H_{2,2} - s)$;

9: $z := H_{2,1}H_{3,2}$;

10: for $k = 0$ to $p - 3$ do

11: Determine the Householder reflector $P$ with $P^T [x; y; z]^T = \alpha e_1$;

12: $r := \max\{1, k\}$;

13: $H_{k+1,k+3,r,n} := P^T H_{k+1,k+3,r,n}$;

14: $r := \min\{k + 4, p\}$;

15: $H_{1,r,k+1+k+3} := H_{1,r,k+1+k+3}P$;

16: $x := H_{k+2,k+1}$; $y := H_{k+3,k+1}$;

17: if $k < p - 3$ then

18: $z := H_{k+4,k+1}$;

19: end if

20: end for

21: Determine the Givens rotation $P$ with $P^T [x; y]^T = \alpha e_1$;

22: $H_{q,p-2,n} := P^T H_{q,p-2,n}$;

23: $H_{1,p,p-1,p} := H_{1,p,p-1,p}P$;

24: /* check for convergence */

25: if $|H_{p,q}| < \varepsilon (|H_{q,q}| + |H_{p,p}|)$ then

26: $H_{p,q} := 0$; $p := p - 1$; $q := p - 1$;

27: else if $|H_{p-1,q-1}| < \varepsilon (|H_{q-1,q-1}| + |H_{q,q}|)$ then

28: $H_{p-1,q-1} := 0$; $p := p - 2$; $q := p - 1$;

29: end if

30: end while

### 4.5.2 The complexity

We first estimate the complexity of a single step of the double step Hessenberg QR algorithm. The most expensive operations are the applications of the $3 \times 3$ Householder reflectors in steps 13 and 15 of Algorithm 4.5. Let us first count the flops for applying the Householder reflector to a 3-vector,

\[x := (I - 2uu^T)x = x - u(2u^Tx).\]

The inner product $u^Tx$ costs 5 flops, multiplying with 2 another one. The operation $x := x - u\gamma$, $\gamma = 2u^Tx$, cost 6 flops, altogether 12 flops.

In the $k$-th step of the loop there are $n - k$ of these application from the left in step 13 and $k + 4$ from the right in step 15. In this step there are thus about $12n + O(1)$ flops to be executed. As $k$ is running from 1 to $p - 3$. We have about $12pn$ flops for this step. Since $p$ runs from $n$ down to about 2 we have $6n^3$ flops. If we assume that two steps are required per eigenvalue the flop count for Francis’ double step QR algorithm to compute all eigenvalues of a real Hessenberg matrix is $12n^3$. If also the eigenvector matrix is accumulated the two additional statements have to be inserted into Algorithm 4.5. After step 15 we have

\[Q_{1:n,k+1:k+3} := Q_{1:n,k+1:k+3}P;\]

and after step 23 we introduce
4.2 We know that Hermitian matrices have a real spectrum.

2.14 If the transformation to tridiagonal form can be accomplished in \( n \) requires another \( 2(n^3) \) update of \( A \).

In the \( k \)-th step of the reduction we similarly have

\[
A_k = P_k^* A_{k-1} P_k = A_{k-1} - u_{k-1} v_{k-1}^* - v_{k-1} u_{k-1}^*,
\]

where the last \( n - k \) elements of \( u_{k-1} \) and \( v_{k-1} \) are nonzero. Forming

\[
v_{k-1} = 2 A_{k-1} u_{k-1} - 2 u_{k-1} (u_{k-1}^* A_{k-1} u_{k-1})
\]

costs \( 2(n-k)^2 + \mathcal{O}(n-k) \) flops. This complexity results from \( A_{k-1} u_{k-1} \). The rank-2 update of \( A_{k-1} \),

\[
A_k = A_{k-1} - u_{k-1} v_{k-1}^* - v_{k-1} u_{k-1}^*,
\]

requires another \( 2(n-k)^2 + \mathcal{O}(n-k) \) flops, taking into account symmetry. By consequence, the transformation to tridiagonal form can be accomplished in

\[
\sum_{k=1}^{n-1} (4(n-k)^2 + \mathcal{O}(n-k)) = \frac{4}{3} n^3 + \mathcal{O}(n^2)
\]
4.6. THE SYMMETRIC TRIDIAGONAL QR ALGORITHM

floating point operations.

4.6.2 The tridiagonal QR algorithm

In the symmetric case the Hessenberg QR algorithm becomes a tridiagonal QR algorithm. This can be executed in an explicit or an implicit way. In the explicit form, a QR step is essentially

1: Choose a shift $\mu$
2: Compute the QR factorization $A - \mu I = QR$
3: Update $A$ by $A = RQ + \mu I$.

Of course, this is done by means of plane rotations and by respecting the symmetric tridiagonal structure of $A$.

In the more elegant implicit form of the algorithm we first compute the first Givens rotation $G_0 = G(1, 2, \vartheta)$ of the QR factorization that zeros the $(2, 1)$ element of $A - \mu I$,

\begin{equation}
\begin{bmatrix}
c & s \\
- \overline{s} & c
\end{bmatrix}
\begin{bmatrix}
a_{11} - \mu \\
a_{21}
\end{bmatrix} =
\begin{bmatrix}
* \\
0
\end{bmatrix}, \quad c = \cos(\vartheta), \quad s = \sin(\vartheta).
\end{equation}

Performing a similar transformation with $G_0$ we have ($n = 5$)

$$G_0^* AG_0 = A' = \begin{bmatrix}
x & x & + \\
\times & \times & \times \\
\times & + & \times & \times & \times \\
\times & \times & \times & \times & \times
\end{bmatrix}$$

Similar as with the double step Hessenberg QR algorithm we chase the bulge down the diagonal. In the $5 \times 5$ example this becomes

$$A \xrightarrow{G_0} G(1, 2, \vartheta_0) \xrightarrow{G_1} G(2, 3, \vartheta_1) \xrightarrow{G_2} G(3, 4, \vartheta_2) \xrightarrow{G_3} G(4, 5, \vartheta_3) = \overline{A}.$$ 

The full step is given by

$$\overline{A} = Q^* AQ, \quad Q = G_0 G_1 \cdots G_{n-2}.$$

Because $G_k e_1 = e_1$ for $k > 0$ we have

$$Q e_1 = G_0 G_1 \cdots G_{n-2} e_1 = G_0 e_1.$$

Both explicit and implicit QR step form the same first plane rotation $G_0$. By referring to the Implicit Q Theorem 4.5 we see that explicit and implicit QR step compute essentially the same $\overline{A}$. 

Algorithm 4.6 Symmetric tridiagonal QR algorithm with implicit Wilkinson shift

1: Let $T \in \mathbb{R}^{n \times n}$ be a symmetric tridiagonal matrix with diagonal entries $a_1, \ldots, a_n$ and off-diagonal entries $b_2, \ldots, b_n$.

This algorithm computes the eigenvalues $\lambda_1, \ldots, \lambda_n$ of $T$ and corresponding eigenvectors $q_1, \ldots, q_n$. The eigenvalues are stored in $a_1, \ldots, a_n$. The eigenvectors are stored in the matrix $Q$, such that $TQ = Q \text{diag}(a_1, \ldots, a_n)$.

2: $m = n$ /* Actual problem dimension. $m$ is reduced in the convergence check. */

3: while $m > 1$ do

4: $d := (a_{m-1} - a_m)/2$; /* Compute Wilkinson’s shift */

5: if $d = 0$ then

6: $s := a_m - |b_m|$;

7: else

8: $s := a_m - b_m^2/(d + \text{sign}(d) \sqrt{d^2 + b_m^2})$;

9: end if

10: $x := a(1) - s$; /* Implicit QR step begins here */

11: $y := b(2)$;

12: for $k = 1$ to $m - 1$ do

13: if $m > 2$ then

14: $[c, s] := \text{givens}(x, y)$;

15: else

16: Determine $[c, s]$ such that $\begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} a_1 \\ b_2 \end{bmatrix} \begin{bmatrix} a_2 \\ c \end{bmatrix}$ is diagonal

17: end if

18: $w := cx - sy$;

19: $d := a_k - a_{k+1}$; $z := (2cb_{k+1} + ds)s$;

20: $a_k := a_k - z$; $a_{k+1} := a_{k+1} + z$;

21: $b_{k+1} := dcs + (c^2 - s^2)b_{k+1}$;

22: $x := b_{k+1}$;

23: if $k > 1$ then

24: $b_k := w$;

25: end if

26: if $k < m - 1$ then

27: $y := -sb_{k+2}$; $b_{k+2} := cb_{k+2}$;

28: end if

29: $Q_{1:n, k:k+1} := Q_{1:n, k:k+1} \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$;

30: end for /* Implicit QR step ends here */

31: if $|b_m| < \varepsilon(|a_{m-1}| + |a_m|)$ then /* Check for convergence */

32: $m := m - 1$;

33: end if

34: end while
Algorithm 4.6 shows the implicit symmetric tridiagonal QR algorithm. The shifts are chosen according to Wilkinson. An issue not treated in this algorithm is deflation. Deflation is of big practical importance. Let us consider the following $6 \times 6$ situation

\[
T = \begin{bmatrix}
a_1 & b_2 & b_3 \\
b_2 & a_2 & 0 & b_5 \\
b_3 & 0 & a_4 & b_6 \\
0 & b_5 & a_5 & b_6 \\
b_6 & a_6 \\
a_6 
\end{bmatrix}.
\]

The shift for the next step is determined from elements $a_5$, $a_6$, and $b_6$. According to (4.12) the first plane rotation is determined from the shift and the elements $a_1$ and $b_1$. The implicit shift algorithm then chases the bulge down the diagonal. In this particular situation, the procedure finishes already in row/column 4 because $b_4 = 0$. Thus the shift which is an approximation to an eigenvalue of the second block (rows 4 to 6) is applied to the wrong first block (rows 1 to 3). Clearly, this shift does not improve convergence.

If the QR algorithm is applied in its explicit form, then still the first block is not treated properly, i.e. with a (probably) wrong shift, but at least the second block is diagonalized rapidly.

Deflation is done as indicated in Algorithm 4.6:

\[
\text{if } |b_k| < \varepsilon(|a_{k-1}| + |a_k|) \text{ then deflate.}
\]

Deflation is particularly simple in the symmetric case since it just means that a tridiagonal eigenvalue problem decouples in two (or more) smaller tridiagonal eigenvalue problems. Notice, however, that the eigenvectors are still $n$ elements long.

4.7 Research

Still today the QR algorithm computes the Schur form of a matrix and is by far the most popular approach for solving dense nonsymmetric eigenvalue problems. Multishift and aggressive early deflation techniques have led to significantly more efficient sequential implementations of the QR algorithm during the last decade. For a brief survey and a discussion of the parallelization of the QR algorithm, see [7].

The three steps of the presented symmetric QR algorithm are (1) reduction of the original matrix to tridiagonal form, (2) computation of the eigenpairs of the tridiagonal matrix, and (3) back-transformation of the eigenvectors. In the ELPA project the first step has been successfully replaced by a two-stage procedure: transformation full to banded, and banded to tridiagonal. This approach improves the utilization of memory hierarchies [8, 3].

4.8 Summary

The QR algorithm is a very powerful algorithm to stably compute the eigenvalues and (if needed) the corresponding eigenvectors or Schur vectors. All steps of the algorithm cost $O(n^3)$ floating point operations, see Table 4.1. The one exception is the case where only eigenvalues are desired of a symmetric tridiagonal matrix. The linear algebra software package LAPACK [1] contains subroutines for all possible ways the QR algorithm may be employed.

Table 4.1: Complexity in flops to compute eigenvalues and eigenvectors/Schur vectors of a real $n \times n$ matrix

We finish by repeating, that the QR algorithm is a method for dense matrix problems. The reduction of a sparse matrix to tridiagonal or Hessenberg form produces fill-in, thus destroying the sparsity structure which one almost always tries to preserve.

Bibliography

Chapter 5

Cuppen’s Divide and Conquer Algorithm

In this chapter we deal with an algorithm that is designed for the efficient solution of the symmetric tridiagonal eigenvalue problem

\[ T \mathbf{x} = \lambda \mathbf{x}, \quad T = \begin{bmatrix} a_1 & b_1 \\ b_1 & a_2 & \ddots \\ & \ddots & \ddots & b \nn-1 \\ b \nn-1 & & a \nn \end{bmatrix}. \]

We noticed from Table 4.1 that the reduction of a full symmetric matrix to a similar tridiagonal matrix requires about \( \frac{2}{3}n^3 \) while the tridiagonal QR algorithm needs an estimated \( 6n^3 \) floating operations (flops) to converge. Because of the importance of this subproblem a considerable effort has been put into finding faster algorithms than the QR algorithms to solve the tridiagonal eigenvalue problem. In the mid-1980’s Dongarra and Sorensen [4] promoted an algorithm originally proposed by Cuppen [2]. This algorithm was based on a divide and conquer strategy. However, it took ten more years until a stable variant was found by Gu and Eisenstat [5, 6]. Today, a stable implementation of this latter algorithm is available in LAPACK [1].

5.1 The divide and conquer idea

Divide and conquer is an old strategy in military to defeat an enemy going back at least to Caesar. In computer science, divide and conquer (D&C) is an important algorithm design paradigm. It works by recursively breaking down a problem into two or more subproblems of the same (or related) type, until these become simple enough to be solved directly. The solutions to the subproblems are then combined to give a solution to the original problem. Translated to our problem the strategy becomes

1. Partition the tridiagonal eigenvalue problem into two (or more) smaller tridiagonal eigenvalue problems.

2. Solve the two smaller problems.

3. Combine the solutions of the smaller problems to get the desired solution of the overall problem.

Evidently, this strategy can be applied recursively.
5.2 Partitioning the tridiagonal matrix

Partitioning the irreducible tridiagonal matrix is done in the following way. We write

\[
T = \begin{bmatrix}
    a_1 & b_1 & & & & & \\
    b_1 & a_2 & \ddots & & & & \\
    \vdots & \ddots & \ddots & \ddots & & & \\
    b_{m-1} & a_m & b_m & & & & \\
    & b_{m+1} & a_{m+2} & \ddots & & & \\
    & & \ddots & \ddots & \ddots & & \\
    & & & b_{n-1} & a_n & b_n & \\
\end{bmatrix}
\]

\[
= \begin{bmatrix}
    a_1 & b_1 & & & & & \\
    b_1 & a_2 & \ddots & & & & \\
    \vdots & \ddots & \ddots & \ddots & & & \\
    b_{m-1} & a_m & b_{m+1} & & & & \\
    b_{m+1} & a_{m+2} & \ddots & & & & \\
    \vdots & \ddots & \ddots & \ddots & & & \\
    b_{n-1} & a_n & b_n & & & & \\
\end{bmatrix}
\]

\[
= \begin{bmatrix}
    T_1 \\ T_2
\end{bmatrix} + \rho uu^T
\]

with \( u = \begin{bmatrix} \pm e_m \\ e_1 \end{bmatrix} \) and \( \rho = \pm b_m \),

where \( e_m \) is a vector of length \( m \approx \frac{n}{2} \) and \( e_1 \) is a vector of length \( n - m \). Notice that the most straightforward way to partition the problem without modifying the diagonal elements leads to a rank-two modification. With the approach of (5.2) we have the original \( T \) as a sum of two smaller tridiagonal systems plus a rank-one modification.

5.3 Solving the small systems

We solve the half-sized eigenvalue problems,

\[
(5.3) \quad T_i = Q_i \Lambda_i Q_i^T, \quad Q_i^T Q_i = I, \quad i = 1, 2.
\]

These two spectral decompositions can be computed by any algorithm, in particular also by this divide and conquer algorithm by which the \( T_i \) would be further split. It is clear that by this partitioning an large number of small problems can be generated that can be potentially solved in parallel. For a parallel algorithm, however, the further phases of the algorithm must be parallelizable as well.

Plugging (5.3) into (5.2) gives

\[
(5.4) \quad \begin{bmatrix} Q_1^T \\ Q_2^T \end{bmatrix} \begin{bmatrix} T_1 \\ T_2 \end{bmatrix} + \rho uu^T \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} = \begin{bmatrix} \Lambda_1 \\ \Lambda_2 \end{bmatrix} + \rho vv^T
\]

with

\[
(5.5) \quad v = \begin{bmatrix} Q_1^T \\ Q_2^T \end{bmatrix} u = \begin{bmatrix} \pm Q_1^T e_m \\ Q_2^T e_1 \end{bmatrix} = \begin{bmatrix} \pm \text{last row of } Q_1 \\ \text{first row of } Q_2 \end{bmatrix}.
\]
Now we have arrived at the eigenvalue problem
\[(D + \rho \mathbf{v}\mathbf{v}^T)\mathbf{x} = \lambda \mathbf{x}, \quad D = \Lambda_1 \oplus \Lambda_2 = \text{diag}(\lambda_1, \ldots, \lambda_n).\]
That is, we have to compute the spectral decomposition of a matrix that is a diagonal plus a rank-one update. Let
\[(5.7) \quad D + \rho \mathbf{v}\mathbf{v}^T = Q\Lambda Q^T\]
be this spectral decomposition. Then, the spectral decomposition of the tridiagonal \(T\) is
\[(5.8) \quad T = \begin{bmatrix} Q_1 & O \\ O & Q_2 \end{bmatrix} Q\Lambda Q^T \begin{bmatrix} Q_1^T \\ O \end{bmatrix}.\]
Forming the product \((Q_1 \oplus Q_2)Q\) will turn out to be the most expensive step of the algorithm. It costs \(n^3 + \mathcal{O}(n^2)\) floating point operations.

5.4 Deflation

There are certain solutions of (5.7) that can be given immediately, by just looking carefully at the equation.

If there are zero entries in \(\mathbf{v}\) then we have
\[(5.9) \quad (v_i = 0 \iff \mathbf{v}^T \mathbf{e}_i = 0) \implies (D + \rho \mathbf{v}\mathbf{v}^T)\mathbf{e}_i = d_i \mathbf{e}_i.\]
Thus, if an entry of \(\mathbf{v}\) vanishes we can read the eigenvalue from the diagonal of \(D\) at once and the corresponding eigenvector is a coordinate vector.

If identical entries occur in the diagonal of \(D\), say \(d_i = d_j\), with \(i < j\), then we can find a plane rotation \(G(i, j, \phi)\) (see (4.4)) such that it introduces a zero into the \(j\)-th position of \(\mathbf{v}\),
\[
G^T \mathbf{v} = G(i, j, \phi)^T \mathbf{v} = \begin{bmatrix} \times \\ \vdots \\ \sqrt{v_i^2 + v_j^2} \\ \vdots \\ 0 \\ \vdots \\ \times \end{bmatrix} \leftarrow \begin{array}{c} i \\ \vdots \\ j \end{array}
\]
Notice, that (for any \(\phi\),
\[
G(i, j, \phi)^T D G(i, j, \phi) = D, \quad d_i = d_j.
\]
So, if there are multiple eigenvalues in \(D\) we can reduce all but one of them by introducing zeros in \(\mathbf{v}\) and then proceed as previously in (5.9).

When working with floating point numbers we deflate if
\[(5.10) \quad |v_i| < C\varepsilon \|T\| \quad \text{or} \quad |d_i - d_j| < C\varepsilon \|T\|, \quad (\|T\| = \|D + \rho \mathbf{v}\mathbf{v}^T\|)
\]
where \(C\) is a small constant. Deflation changes the eigenvalue problem for \(D + \rho \mathbf{v}\mathbf{v}^T\) into the eigenvalue problem for
\[(5.11) \quad \begin{bmatrix} D_1 + \rho \mathbf{v}_1\mathbf{v}_1^T \\ O \\ O \\ D_2 \end{bmatrix} = G^T (D + \rho \mathbf{v}\mathbf{v}^T) G + \mathbf{E}, \quad \|\mathbf{E}\| < C\varepsilon \sqrt{\|D\|^2 + |\rho|^2 \|\mathbf{v}\|^4},
\]
where \(D_1\) has no multiple diagonal entries and \(\mathbf{v}_1\) has no zero entries. So, we have to compute the spectral decomposition of the matrix in (5.11) which is similar to a slight perturbation of the original matrix. \(G\) is the product of Givens rotations.
5.4.1 Numerical examples

Let us first consider

\[
T = \begin{bmatrix}
1 & 1 & 1 \\
1 & 2 & 1 \\
1 & 3 & 1 \\
1 & 4 & 1 \\
1 & 5 & 1 \\
1 & 6 & 1 \\
\end{bmatrix} = \begin{bmatrix}
1 & 1 & 0 \\
1 & 2 & 0 \\
0 & 3 & 1 \\
0 & 1 & 5 \\
0 & 1 & 6 \\
\end{bmatrix} + \begin{bmatrix}
0 & 1 & 0 \\
1 & 1 & 0 \\
0 & 1 & 0 \\
0 & 1 & 0 \\
0 & 1 & 0 \\
\end{bmatrix} = T_0 + uu^T.
\]

Then a little MATLAB experiment shows that

\[
Q_0^T T Q_0 = \begin{bmatrix}
0.1981 & 1.5550 & 3.2470 \\
2.5395 & 4.7609 & 6.6996 \\
\end{bmatrix} + \begin{bmatrix}
0.3280 & 0.7370 & 0.5910 \\
0.9018 & -0.4042 & 0.1531 \\
\end{bmatrix}^T
\]

with

\[
Q_0 = \begin{bmatrix}
0.7370 & -0.5910 & 0.3280 \\
-0.5910 & -0.3280 & 0.7370 \\
0.3280 & 0.7370 & 0.5910 \\
0.9018 & -0.4153 & 0.1200 \\
-0.4042 & -0.7118 & 0.5744 \\
0.1531 & 0.5665 & 0.8097 \\
\end{bmatrix}
\]

Here it is not possible to deflate.

Let us now look at an example with more symmetry,

\[
T = \begin{bmatrix}
2 & 1 & 1 \\
1 & 2 & 1 \\
1 & 2 & 1 \\
1 & 2 & 1 \\
1 & 2 & 1 \\
1 & 2 & 1 \\
\end{bmatrix} = \begin{bmatrix}
2 & 1 & 1 \\
1 & 2 & 1 \\
0 & 1 & 1 \\
0 & 1 & 2 \\
0 & 1 & 2 \\
0 & 1 & 2 \\
\end{bmatrix} + \begin{bmatrix}
0 & 1 & 0 \\
1 & 1 & 0 \\
0 & 1 & 0 \\
0 & 1 & 0 \\
0 & 1 & 0 \\
0 & 1 & 0 \\
\end{bmatrix} = T_0 + uu^T.
\]
5.5. THE EIGENVALUE PROBLEM FOR $D + \rho \mathbf{vv}^T$

Now, MATLAB gives

\[
Q_0^T TQ_0 = \begin{bmatrix}
0.1981 & 1.5550 & 3.2470 \\
1.5550 & 0.1981 & 1.5550 \\
3.2470 & 1.5550 & 3.2470 \\
\end{bmatrix} + \begin{bmatrix}
0.7370 & -0.5910 & 0.3280 \\
-0.5910 & 0.3280 & 0.7370 \\
0.3280 & 0.7370 & -0.5910 \\
\end{bmatrix}^T
\]

with

\[
Q_0 = \begin{bmatrix}
0.3280 & 0.7370 & 0.5910 \\
-0.5910 & -0.3280 & 0.7370 \\
0.7370 & -0.5910 & 0.3280 \\
\end{bmatrix}
\]

In this example we have three double eigenvalues. Because the corresponding components of $\mathbf{v}$ ($v_i$ and $v_{i+1}$) are equal we define

\[
G = G(1,4,\pi/4)G(2,5,\pi/4)G(3,6,\pi/4)
\]

\[
= \begin{bmatrix}
0.7071 & 0.7071 & 0.7071 \\
0.7071 & 0.7071 & 0.7071 \\
-0.7071 & -0.7071 & -0.7071 \\
\end{bmatrix}
\]

Then,

\[
G^T Q_0^T TQ_0 G = G^T Q_0^T T_0 Q_0 G + G^T \mathbf{v}(G^T \mathbf{v})^T = D + G^T \mathbf{v}(G^T \mathbf{v})^T
\]

\[
= \begin{bmatrix}
0.1981 & 1.5550 & 3.2470 \\
1.5550 & 0.1981 & 1.5550 \\
3.2470 & 1.5550 & 3.2470 \\
\end{bmatrix} + \begin{bmatrix}
1.0422 & 0.4638 & 0.0000 \\
-0.8358 & 0.4638 & 0.0000 \\
0.0000 & 0.0000 & 0.0000 \\
\end{bmatrix}^T
\]

Therefore, (in this example) $\mathbf{e}_4$, $\mathbf{e}_5$, and $\mathbf{e}_6$ are eigenvectors of

\[
D + G^T \mathbf{v}(G^T \mathbf{v})^T = D + G^T \mathbf{vv}^T G
\]

corresponding to the eigenvalues $d_4$, $d_5$, and $d_6$, respectively. The eigenvectors of $T$ corresponding to these three eigenvalues are the last three columns of

\[
Q_0 G = \begin{bmatrix}
0.2319 & -0.4179 & 0.5211 & 0.5211 & -0.4179 & 0.2319 \\
0.5211 & -0.2319 & -0.4179 & -0.4179 & -0.2319 & 0.5211 \\
0.4179 & 0.5211 & 0.2319 & 0.2319 & 0.5211 & 0.4179 \\
-0.2319 & 0.4179 & -0.5211 & 0.5211 & -0.4179 & 0.2319 \\
-0.5211 & 0.2319 & 0.4179 & -0.4179 & -0.2319 & 0.5211 \\
-0.4179 & -0.5211 & -0.2319 & 0.2319 & 0.5211 & 0.4179 \\
\end{bmatrix}
\]

5.5 The eigenvalue problem for $D + \rho \mathbf{vv}^T$

We know that $\rho \neq 0$. Otherwise there is nothing to be done. Furthermore, after deflation, we know that all elements of $\mathbf{v}$ are nonzero and that the diagonal elements of $D$ are all
distinct, in fact,

\[ |d_i - d_j| > C\varepsilon\|T\|. \]

We order the diagonal elements of \( D \) such that

\[ d_1 < d_2 < \cdots < d_n. \]

Notice that this procedure permutes the elements of \( v \) as well. Let \((\lambda, x)\) be an eigenpair of

\[ (5.12) \quad (D + \rho vv^T)x = \lambda x. \]

Then,

\[ (5.13) \quad (D - \lambda I)x = -\rho vv^T x. \]

\( \lambda \) cannot be equal to one of the \( d_i \). If \( \lambda = d_k \) then the \( k \)-th element on the left of (5.13) vanishes. But then either \( v_k = 0 \) or \( v^T x = 0 \). The first cannot be true for our assumption about \( v \). If on the other hand \( v^T x = 0 \) then \( (D - d_k I)x = 0 \). Thus \( x = e_k \) and \( v^T e_k = v_k = 0 \), which cannot be true. Therefore \( D - \lambda I \) is nonsingular and

\[ (5.14) \quad x = \rho (\lambda I - D)^{-1} v(v^T x). \]

This equation shows that \( x \) is proportional to \((\lambda I - D)^{-1} v\). If we require \( \|x\| = 1 \) then

\[ (5.15) \quad x = \frac{(\lambda I - D)^{-1} v}{\| (\lambda I - D)^{-1} v \|}. \]

Multiplying (5.14) by \( v^T \) from the left we get

\[ (5.16) \quad v^T x = \rho v^T (\lambda I - D)^{-1} v(v^T x). \]

Since \( v^T x \neq 0 \), \( \lambda \) is an eigenvalue of (5.12) if and only if

\[ f(\lambda) := 1 - \rho v^T (\lambda I - D)^{-1} v = 1 - \rho \sum_{k=1}^{n} \frac{v_k^2}{\lambda - d_k} = 0. \]
5.5. THE EIGENVALUE PROBLEM FOR $D + \rho VV^T$

This equation is called secular equation. The secular equation has poles at the eigenvalues of $D$ and zeros at the eigenvalues of $D + \rho VV^T$. Notice that

$$f'(\lambda) = \rho \sum_{k=1}^{n} \frac{v_k^2}{(\lambda - d_k)^2},$$

Thus, the derivative of $f$ is positive if $\rho > 0$ wherever it has a finite value. If $\rho < 0$ the derivative of $f$ is negative (almost) everywhere. A typical graph of $f$ is depicted in Fig. 5.1. (If $\rho$ is negative the image can be flipped left to right.) The secular equation implies the interlacing property of the eigenvalues of $D$ and of $D + \rho VV^T$,

$$d_1 < \lambda_1 < d_2 < \lambda_2 < \cdots < d_n < \lambda_n, \quad \rho > 0.$$  \hfill (5.18)

or

$$\lambda_1 < d_1 < \lambda_2 < d_2 < \cdots < \lambda_n < d_n, \quad \rho < 0.$$  \hfill (5.19)

So, we have to compute one eigenvalue in each of the intervals $(d_i, d_{i+1})$, $1 \leq i < n$, and a further eigenvalue in $(d_n, \infty)$ or $(-\infty, d_1)$. The corresponding eigenvector is then given by (5.15). Evidently, these tasks are easy to parallelize.

Equations (5.17) and (5.15) can also be obtained from the relations

$$\begin{bmatrix} \frac{1}{\rho} & V^T \\ V & \lambda I - D \end{bmatrix} = \begin{bmatrix} 1 & 0^T \\ \rho V & I \end{bmatrix} \begin{bmatrix} \frac{1}{\rho} & 0^T \\ 0 & \lambda I - D - \rho VV^T \end{bmatrix} \begin{bmatrix} 1 & \rho V^T \\ 0 & I \end{bmatrix}$$

$$= \begin{bmatrix} 1 & V^T(\lambda I - D)^{-1} \\ 0 & I \end{bmatrix} \begin{bmatrix} \frac{1}{\rho} - V^T(\lambda I - D)^{-1}V & 0^T \\ 0 & \lambda I - D \end{bmatrix} \begin{bmatrix} 1 & 0^T \\ (\lambda I - D)^{-1}V & I \end{bmatrix}.$$  

These are simply block $LDL^T$ factorizations of the first matrix. The first is the well-known one where the factorization is started with the $(1,1)$ block. The second is a ‘backward’ factorization that is started with the $(2,2)$ block. Because the determinants of the tridiagonal matrices are all unity, we have

$$\frac{1}{\rho} \det(\lambda I - D - \rho VV^T) = \frac{1}{\rho} (1 - \rho V^T(\lambda I - D)^{-1}V) \det(\lambda I - D).$$  \hfill (5.20)

Denoting the eigenvalues of $D + \rho VV^T$ again by $\lambda_1 < \lambda_2 < \cdots < \lambda_n$ this implies

$$\prod_{j=1}^{n} (\lambda - \lambda_j) = (1 - \rho V^T(\lambda I - D)^{-1}V) \prod_{j=1}^{n} (\lambda - d_j)$$

$$= \left(1 - \rho \sum_{k=1}^{n} \frac{v_k^2}{\lambda - d_k} \right) \prod_{j=1}^{n} (\lambda - d_j)$$

$$= \prod_{j=1}^{n} (\lambda - d_j) - \rho \sum_{k=1}^{n} \frac{v_k^2}{\lambda - d_k} \prod_{j \neq k} (\lambda - d_j)$$

Setting $\lambda = d_k$ gives

$$\prod_{j=1}^{n} (d_k - \lambda_j) = -\rho v_k^2 \prod_{j \neq k}^{n} (d_k - d_j).$$  \hfill (5.22)
\[ v_k^2 = \frac{1}{\rho} \prod_{j=1}^{n} (d_k - \lambda_j) \prod_{j=1}^{n} (\lambda_j - d_j) = \frac{1}{\rho} \prod_{j=1}^{k-1} (d_k - \lambda_j) \prod_{j=k}^{n} (\lambda_j - d_k)(-1)^{n-k+1} \]

or

\[ v_k^2 = \frac{1}{\rho} \prod_{j=1}^{n} (d_k - \lambda_j) \prod_{j=1}^{n} (\lambda_j - d_j) = \frac{1}{\rho} \prod_{j=1}^{k-1} (d_k - \lambda_j) \prod_{j=k+1}^{n} (d_j - d_k)(-1)^{n-k} \]

Therefore, the quantity on the right side is positive, so

\[ v_k = \sqrt{\frac{1}{\rho} \prod_{j=1}^{k-1} (d_k - \lambda_j) \prod_{j=k+1}^{n} (d_j - d_k)} \]

(Similar arguments hold if \( \rho < 0 \).) Thus, we have the solution of the following inverse eigenvalue problem:

Given \( D = \text{diag}(d_1, \ldots, d_n) \) and values \( \lambda_1, \ldots, \lambda_n \) that satisfy (5.18). Find a vector \( v = [v_1, \ldots, v_n]^T \) with positive components \( v_k \) such that the matrix \( D + vv^T \) has the prescribed eigenvalues \( \lambda_1, \ldots, \lambda_n \).

The solution is given by (5.24). The positivity of the \( v_k \) makes the solution unique.

5.6 Solving the secular equation

In this section we follow closely the exposition of Demmel [3]. We consider the computation of the zero of \( f(\lambda) \) in the interval \((d_i, d_{i+1})\). We assume that \( \rho = 1 \).

We may simply apply Newton’s iteration to solve \( f(\lambda) = 0 \). However, if we look carefully at Fig. 5.1 then we notice that the tangent at certain points in \((d_i, d_{i+1})\) crosses the real axis outside this interval. This happens in particular if the weights \( v_i \) or \( v_{i+1} \) are small. Therefore that zero finder has to be adapted in such a way that it captures the poles at the interval endpoints. It is relatively straightforward to try the ansatz

\[ h(\lambda) = \frac{c_1}{d_i - \lambda} + \frac{c_2}{d_{i+1} - \lambda} + c_3. \]

Notice that, given the coefficients \( c_1, c_2, \) and \( c_3 \), the equation \( h(\lambda) = 0 \) can easily be solved by means of the equivalent quadratic equation

\[ c_1(d_{i+1} - \lambda) + c_2(d_i - \lambda) + c_3(d_i - \lambda)(d_{i+1} - \lambda) = 0. \]

This equation has two zeros. Precisely one of them is inside \((d_i, d_{i+1})\).

The coefficients \( c_1, c_2, \) and \( c_3 \) are computed in the following way. Let us assume that we have available an approximation \( \lambda_j \) to the zero in \((d_i, d_{i+1})\). We request that \( h(\lambda_j) = f(\lambda_j) \) and \( h'(\lambda_j) = f'(\lambda_j) \). The exact procedure is as follows. We write

\[ f(\lambda) = 1 + \sum_{k=1}^{i} \frac{v_k^2}{d_k - \lambda} + \sum_{k=i+1}^{n} \frac{v_k^2}{d_k - \lambda} = 1 + \psi_1(\lambda) + \psi_2(\lambda). \]
5.7. A FIRST ALGORITHM

ψ₁(λ) is a sum of positive terms and ψ₂(λ) is a sum of negative terms. Both ψ₁(λ) and ψ₂(λ) can be computed accurately, whereas adding them would likely provoke cancellation and loss of relative accuracy. We now choose c₁ and \( \hat{c}_1 \) such that

\[
(5.28) \quad h_1(\lambda) := \hat{c}_1 + \frac{c_1}{d_i - \lambda} \text{ satisfies } h_1(\lambda_j) = \psi_1(\lambda_j) \text{ and } h'_1(\lambda_j) = \psi'_1(\lambda_j).
\]

This means that the graphs of \( h_1 \) and of \( \psi_1 \) are tangent at \( \lambda = \lambda_j \). This is similar to Newton’s method. However in Newton’s method a straight line is fitted to the given function. The coefficients in (5.28) are given by

\[
c_1 = \psi'_1(\lambda_j)(d_i - \lambda_j)^2 > 0,
\]

\[
\hat{c}_1 = \psi_1(\lambda_j) - \psi'_1(\lambda_j)(d_i - \lambda_j) = \sum_{k=1}^{i} v_k^2 \left( \frac{d_k - d_i}{(d_k - \lambda_j)^2} \right) \leq 0.
\]

Similarly, the two constants \( c_2 \) and \( \hat{c}_2 \) are determined such that

\[
(5.29) \quad h_2(\lambda) := \hat{c}_2 + \frac{c_2}{d_{i+1} - \lambda} \text{ satisfies } h_2(\lambda_j) = \psi_2(\lambda_j) \text{ and } h'_2(\lambda_j) = \psi'_2(\lambda_j)
\]

with the coefficients

\[
c_2 = \psi'_2(\lambda_j)(d_{i+1} - \lambda_j)^2 > 0,
\]

\[
\hat{c}_2 = \psi_2(\lambda_j) - \psi'_2(\lambda_j)(d_{i+1} - \lambda_j) = \sum_{k=i+1}^{n} v_k^2 \left( \frac{d_k - d_{i+1}}{(d_k - \lambda_j)^2} \right) \geq 0.
\]

Finally, we set

\[
(5.30) \quad h(\lambda) = 1 + h_1(\lambda) + h_2(\lambda) = (1 + \hat{c}_1 + \hat{c}_2) + \frac{c_1}{c_3} \frac{d_i - \lambda}{d_i - \lambda} + \frac{c_2}{d_{i+1} - \lambda}.
\]

This zero finder is converging quadratically to the desired zero [7]. Usually 2 to 3 steps are sufficient to get the zero to machine precision. Therefore finding a zero only requires O(\( n \)) flops. Thus, finding all zeros costs O(\( n^2 \)) floating point operations.

5.7 A first algorithm

We are now ready to give the divide and conquer algorithm, see Algorithm 5.1.

All steps except step 10 require O(\( n^2 \)) operations to complete. The step 10 costs \( n^3 \) flops. Thus, the full divide and conquer algorithm, requires

\[
T(n) = n^3 + 2 \cdot T(n/2) = n^3 + 2 \left( \frac{n}{2} \right)^3 + 4T(n/4)
\]

\[
= n^3 + \frac{n^3}{4} + 4 \left( \frac{n}{4} \right)^3 + 8T(n/8) = \cdots = 4 \cdot \frac{n^3}{3}.
\]

This serial complexity of the algorithm very often overestimates the computational costs of the algorithm due to significant deflation that is observed surprisingly often.
Algorithm 5.1 The tridiagonal divide and conquer algorithm

1: Let $T \in \mathbb{C}^{n \times n}$ be a real symmetric tridiagonal matrix. This algorithm computes the spectral decomposition of $T = Q\Lambda Q^T$, where the diagonal $\Lambda$ is the matrix of eigenvalues and $Q$ is orthogonal.

2: if $T$ is $1 \times 1$ then
3: \textbf{return} $(\Lambda = T; Q = 1)$
4: else
5: Partition $T = \begin{bmatrix} T_1 & O \\ O & T_2 \end{bmatrix} + \rho uu^T$ according to (5.2)
6: Call this algorithm with $T_1$ as input and $Q_1$, $\Lambda_1$ as output.
7: Call this algorithm with $T_2$ as input and $Q_2$, $\Lambda_2$ as output.
8: Form $D + \rho vv^T$ from $\Lambda_1$, $\Lambda_2$, $Q_1$, $Q_2$ according to (5.4)–(5.6).
9: Find the eigenvalues $\Lambda$ and the eigenvectors $Q'$ of $D + \rho vv^T$.
10: Form $Q = \begin{bmatrix} Q_1 & O \\ O & Q_2 \end{bmatrix} \cdot Q'$ which are the eigenvectors of $T$.
11: \textbf{return} $(\Lambda; Q)$
12: end if

5.7.1 A numerical example

Let $A$ be a $4 \times 4$ matrix

$$A = D + vv^T = \begin{bmatrix} 0 & 2-\beta & 2+\beta & 5 \\ 2-\beta & 0 & \beta & 5 \\ 2+\beta & \beta & 0 & 5 \\ 5 & 5 & 5 & 0 \end{bmatrix}.$$ \hspace{1cm} (5.32)

In this example (that is similar to one in [8]) we want to point at a problem that the divide and conquer algorithm possesses as it is given in Algorithm 5.1, namely the loss of orthogonality among eigenvectors.

Before we do some MATLAB tests let us look more closely at $D$ and $v$ in (5.32). This example becomes difficult to solve if $\beta$ gets very small. In Figures 5.2 to 5.5 we see graphs of the function $f_\beta(\lambda)$ that appears in the secular equation for $\beta = 1$, $\beta = 0.1$, and $\beta = 0.01$. The critical zeros move towards 2 from both sides. The weights $v_2^2 = v_3^2 = \beta^2$ are however not so small that they should be deflated.

The following MATLAB code shows the problem. We execute the commands for $\beta = 10^{-k}$ for $k = 0, 1, 2, 4, 8$.

```matlab
v = [1 beta beta 1]'; % rank-1 modification
d = [0, 2-beta, 2*beta, 5]'; % diagonal matrix
L = eig(diag(d) + v*v') % eigenvalues of the modified matrix
e = ones(4,1);
q = (d*e'-e*L')./(v*e'); % unnormalized eigenvectors cf. (5.15)
Q = sqrt(diag(q'*q));
q = q./(e*Q'); % normalized eigenvectors
norm(q'*q-eye(4)) % check for orthogonality
```

We do not bother how we compute the eigenvalues. We simply use MATLAB's built-in function \texttt{eig}. We get the results of Table 5.1.
5.7. A FIRST ALGORITHM

We observe loss of orthogonality among the eigenvectors as the eigenvalues get closer and closer. This may not be surprising as we compute the eigenvectors by formula (5.15)

\[ \mathbf{x} = \frac{(\lambda I - D)^{-1}\mathbf{v}}{\| (\lambda I - D)^{-1}\mathbf{v} \|}. \]

If \( \lambda = \lambda_2 \) and \( \lambda = \lambda_3 \) which are almost equal, \( \lambda_2 \approx \lambda_3 \) then intuitively one expects almost the same eigenvectors. We have in fact

\[
Q^T Q - I_4 = \begin{bmatrix}
-2.2204 \cdot 10^{-16} & 4.3553 \cdot 10^{-8} & 1.7955 \cdot 10^{-8} & -1.1102 \cdot 10^{-16} \\
4.3553 \cdot 10^{-8} & 0 & -5.5511 \cdot 10^{-8} & -1.8298 \cdot 10^{-8} \\
1.7955 \cdot 10^{-8} & -5.5511 \cdot 10^{-8} & -1.1102 \cdot 10^{-16} & -7.5437 \cdot 10^{-9} \\
-1.1102 \cdot 10^{-16} & -1.8298 \cdot 10^{-8} & -7.5437 \cdot 10^{-9} & 0
\end{bmatrix}.
\]

Orthogonality is lost only with respect to the vectors corresponding to the eigenvalues close to 2.
Already Dongarra and Sorensen [4] analyzed this problem. In their formulation they normalize the vector $v$ of $D + \rho v v^T$ to have norm unity, $\|v\| = 1$. They stated

**Lemma 5.1** Let

$$q_\lambda^T = \left( \frac{v_1}{d_1 - \lambda}, \frac{v_2}{d_2 - \lambda}, \ldots, \frac{v_n}{d_n - \lambda} \right) \left[ \frac{\rho}{f'(\lambda)} \right]^{1/2}. \tag{5.33}$$

Then for any $\lambda, \mu \notin \{d_1, \ldots, d_n\}$ we have

$$|q_\lambda^T q_\mu| = \frac{1}{|\lambda - \mu| \left| f'(\lambda) f'(\mu) \right|^{1/2}} |f(\lambda) - f(\mu)|. \tag{5.34}$$

**Proof.** Observe that

$$\frac{\lambda - \mu}{(d_j - \lambda)(d_j - \mu)} = \frac{1}{d_j - \lambda} - \frac{1}{d_j - \mu}. \tag{5.35}$$

Then the proof is straightforward.
5.8 The algorithm of Gu and Eisenstat

Computing eigenvector according to the formula

\[
(5.35) \quad x = \alpha (\lambda I - D)^{-1} v = \alpha \begin{pmatrix}
\frac{v_1}{\lambda - d_1} \\
\vdots \\
\frac{v_n}{\lambda - d_n}
\end{pmatrix}, \quad \alpha = \| (\lambda I - D)^{-1} v \|,
\]

is bound to fail if \( \lambda \) is very close to a pole \( d_k \) and the difference \( \lambda - d_k \) has an error of size \( O(\varepsilon |d_k|) \) instead of only \( O(\varepsilon|d_k - \lambda|) \). To resolve this problem Gu and Eisenstat [5] found a trick that is at the same time ingenious and simple.

They observed that the \( v_k \) in (5.24) are very accurately determined by the data \( d_i \) and \( \lambda_i \). Therefore, once the eigenvalues are computed accurately a vector \( \hat{v} \) could be computed such that the \( \lambda_i \) are accurate eigenvalues of \( D + \hat{v}\hat{v} \). If \( \hat{v} \) approximates well the original \( v \) then the new eigenvectors will be the exact eigenvectors of a slightly modified eigenvalue problem, which is all we can hope for.

The zeros of the secular equation can be computed accurately by the method presented in section 5.6. However, a shift of variables is necessary. In the interval \((d_i, d_{i+1})\) the origin of the real axis is moved to \( d_i \) if \( \lambda_i \) is closer to \( d_i \) than to \( d_{i+1} \), i.e., if \( f((d_i + d_{i+1})/2) > 0 \). Otherwise, the origin is shifted to \( d_{i+1} \). This shift of the origin avoids the computation of the smallest difference \( d_i - \lambda \) (or \( d_{i+1} - \lambda \)) in (5.35), thus avoiding cancellation in this most sensitive quantity. Equation (5.26) can be rewritten as

\[
(5.36) \quad \frac{c_1 \Delta_{i+1} + c_2 \Delta_i + c_3 \Delta_i \Delta_{i+1}}{b} - \frac{c_1 + c_2 + c_3 (\Delta_i + \Delta_{i+1})}{a} \eta + \frac{c_3}{c} \eta^2 = 0,
\]

where \( \Delta_i = d_i - \lambda_j, \Delta_{i+1} = d_{i+1} - \lambda_j, \) and \( \lambda_{j+1} = \lambda_j + \eta \) is the next approximate zero. With equations (5.28)–(5.30) the coefficients in (5.36) get

\[
a = c_1 + c_2 + c_3 (\Delta_i + \Delta_{i+1}) = (1 + \Psi_1 + \Psi_2) (\Delta_i + \Delta_{i+1}) - (\Psi'_1 + \Psi'_2) \Delta_i \Delta_{i+1},
\]

\[
b = c_1 \Delta_{i+1} + c_2 \Delta_i + c_3 \Delta_i \Delta_{i+1} = \Delta_i \Delta_{i+1} (1 + \Psi_1 + \Psi_2),
\]

\[
c = c_3 = 1 + \Psi_1 + \Psi_2 - \Delta_i \Psi'_1 - \Delta_{i+1} \Psi'_2.
\]
If we are looking for a zero that is closer to \( d_i \) than to \( d_{i+1} \) then we move the origin to \( \lambda_j \), i.e., we have e.g. \( \Delta_i = -\lambda_j \). The solution of (5.36) that lies inside the interval is

\[
\eta = \begin{cases} 
  a - \sqrt{a^2 - 4bc} & \text{if } a \leq 0, \\
  a + \sqrt{a^2 - 4bc} & \text{if } a > 0.
\end{cases}
\]

The following algorithm shows how step 9 of the tridiagonal divide and conquer algorithm 5.1 must be implemented.

**Algorithm 5.2 A stable eigensolver for \( D + vv^T \)**

1. This algorithm stably computes the spectral decomposition of \( D + vv^T = QAQ^T \) where \( D = \text{diag}(d_1, \ldots, d_n), v = [v_1, \ldots, v_n] \in \mathbb{R}^n, \Lambda = \text{diag}(\lambda_1, \ldots, \lambda_n), \) and \( Q = [q_1, \ldots, q_n] \).
2. \( d_{i+1} = d_n + \|v\|^2 \).
3. In each interval \((d_i, d_{i+1})\) compute the zero \( \lambda_i \) of the secular equation \( f(\lambda) = 0 \).
4. Use the formula (5.24) to compute the vector \( \hat{v} \) such that the \( \lambda_i \) are the ‘exact’ eigenvalues of \( D + \hat{v}\hat{v} \).
5. In each interval \((d_i, d_{i+1})\) compute the eigenvectors of \( D + \hat{v}\hat{v} \) according to (5.15),

\[
q_i = \frac{(\lambda_i I - D)^{-1}\hat{v}}{\| (\lambda_i I - D)^{-1}\hat{v} \|}.
\]

6. return \((\Lambda; Q)\)

### 5.8.1 A numerical example [continued]

We continue the discussion of the example on page 100 where the eigenvalue problem of

\[
A = D + vv^T = \begin{bmatrix}
0 & 2 - \beta \\
2 + \beta & 5
\end{bmatrix} + \begin{bmatrix}
1 \\
\beta \\
\beta \\
1
\end{bmatrix} \begin{bmatrix}
1 & \beta & \beta & 1
\end{bmatrix}.
\]

The MATLAB code that we showed did not give orthogonal eigenvectors. We show in the following script that the formulae (5.24) really solve the problem.

```matlab
dlam = zeros(n,1);
for k=1:n,
    [dlam(k), dvec(:,k)] = zerodandc(d,v,k);
end

V = ones(n,1);
for k=1:n,
    V(k) = prod(abs(dvec(k,:)))/prod(d(k) - d(1:k-1))/prod(d(k+1:n) - d(k));
    V(k) = sqrt(V(k));
end

Q = (dvec)./(V*e');
diagq = sqrt(diag(Q'*Q));
Q = Q./(e*diagq');
```
for k=1:n,
    if dlam(k)>0,
        dlam(k) = dlam(k) + d(k);
    else
        dlam(k) = d(k+1) + dlam(k);
    end
end

\[ \text{norm}(Q'Q - \text{eye}(n)) \]
\[ \text{norm}((\text{diag}(d) + v*v')*Q - Q*\text{diag}(dlam')) \]

A zero finder returns for each interval the quantity \( \lambda_i - d_i \) and the vector \([d_1 - \lambda_i, \ldots, d_n - \lambda_i]^T\) to high precision. These vector elements have been computed as \((d_k - d_i) - (\lambda_i - d_i)\). The zerofinder of Li [7] has been employed here. At the end of this section we list the zerofinder written in MATLAB that was used here. The formulae (5.37) and (5.38) have been used to solve the quadratic equation (5.36). Notice that only one of the while loops is traversed, depending on if the zero is closer to the pole on the left or to the right of the interval. The \(v_k\) of formula (5.24) are computed next. \(Q\) contains the eigenvectors.

Table 5.2: Loss of orthogonality among the eigenvectors computed by the straightforward algorithm (I) and the Gu-Eisenstat approach (II)

Again we ran the code for \(\beta = 10^{-k}\) for \(k = 0, 1, 2, 4, 8\). The numbers in Table 5.2 confirm that the new formulae are much more accurate than the straightforward ones. The norms of the errors obtained for the Gu-Eisenstat algorithm always are in the order of machine precision, i.e., \(10^{-16}\).

Note that there may be errors in the following code! The vector \(v\) is squared on the 3rd line, and later (assigning values to \(di1, psi1, psi2\)) squared again!

```matlab
function [lambda,dl] = zerodandc(d,v,i)
% ZERODANDC - Computes eigenvalue lambda in the i-th interval
% (d(i), d(i+1)) with Li's 'middle way' zero finder
% dl is the n-vector [d(1..n) - lambda]

n = length(d);
di = d(i);
v = v.^2;
if i < n,
    di1 = d(i+1); lambda = (di + di1)/2;
else
    di1 = d(n) + norm(v)^2; lambda = di1;
```
end
eta = 1;
psi1 = sum((v(1:i).^2)./(d(1:i) - lambda));
psi2 = sum((v(i+1:n).^2)./(d(i+1:n) - lambda));

if 1 + psi1 + psi2 > 0, % zero is on the left half of the interval
    d = d - di; lambda = lambda - di; di1 = di1 - di; di = 0;
    while abs(eta) > 10*eps
        psi1 = sum(v(1:i)./(d(1:i) - lambda));
        psi1s = sum(v(1:i)./((d(1:i) - lambda)).^2);
        psi2 = sum((v(i+1:n))./(d(i+1:n) - lambda));
        psi2s = sum(v(i+1:n)./((d(i+1:n) - lambda)).^2);
        % Solve for zero
        Di = -lambda; Di1 = di1 - lambda;
        a = (Di + Di1)*(1 + psi1 + psi2) - Di*Di1*(psi1s + psi2s);
        b = Di*Di1*(1 + psi1 + psi2);
        c = (1 + psi1 + psi2) - Di*psi1s - Di1*psi2s;
        if a > 0,
            eta = (2*b)/(a + sqrt(a^2 - 4*b*c));
        else
            eta = (a - sqrt(a^2 - 4*b*c))/(2*c);
        end
        lambda = lambda + eta;
    end
else % zero is on the right half of the interval

Chapter 6

LAPACK and the BLAS

6.1 LAPACK

(This section is essentially compiled from the LAPACK User’s Guide [1] that is available online from http://www.netlib.org/lapack/lug/.)

LAPACK [1] is a library of Fortran 77 subroutines for solving the most commonly occurring problems in numerical linear algebra. It has been designed to be efficient on a wide range of modern high-performance computers. The name LAPACK is an acronym for Linear Algebra PACKage.

LAPACK can solve systems of linear equations, linear least squares problems, eigenvalue problems and singular value problems. LAPACK can also handle many associated computations such as matrix factorizations or estimating condition numbers.

LAPACK contains driver routines for solving standard types of problems, computational routines to perform a distinct computational task, and auxiliary routines to perform a certain subtask or common low-level computation. Each driver routine typically calls a sequence of computational routines. Taken as a whole, the computational routines can perform a wider range of tasks than are covered by the driver routines. Many of the auxiliary routines may be of use to numerical analysts or software developers, so we have documented the Fortran source for these routines with the same level of detail used for the LAPACK routines and driver routines.

Dense and banded matrices are provided for, but not general sparse matrices. In all areas, similar functionality is provided for real and complex matrices.

LAPACK is designed to give high efficiency on vector processors, high-performance “super-scalar” workstations, and shared memory multiprocessors. It can also be used satisfactorily on all types of scalar machines (PC’s, workstations, mainframes). A distributed-memory version of LAPACK, ScaLAPACK [2], has been developed for other types of parallel architectures (for example, massively parallel SIMD machines, or distributed memory machines).

LAPACK has been designed to supersede LINPACK [3] and EISPACK [10, 8], principally by restructuring the software to achieve much greater efficiency, where possible, on modern high-performance computers; also by adding extra functionality, by using some new or improved algorithms, and by integrating the two sets of algorithms into a unified package.

LAPACK routines are written so that as much as possible of the computation is performed by calls to the Basic Linear Algebra Subprograms (BLAS) [9, 6, 5]. Highly efficient machine-specific implementations of the BLAS are available for many modern
high-performance computers. The BLAS enable LAPACK routines to achieve high performance with portable code.

The BLAS are not strictly speaking part of LAPACK, but Fortran 77 code for the BLAS is distributed with LAPACK, or can be obtained separately from netlib where “model implementations” are found.

The model implementation is not expected to perform as well as a specially tuned implementation on most high-performance computers – on some machines it may give much worse performance – but it allows users to run LAPACK codes on machines that do not offer any other implementation of the BLAS.

The complete LAPACK package or individual routines from LAPACK are freely available from the World Wide Web or by anonymous ftp. The LAPACK homepage can be accessed via the URL \url{http://www.netlib.org/lapack/}.

6.2 BLAS

By 1976 it was clear that some standardization of basic computer operations on vectors was needed \cite{9}. By then it was already known that coding procedures that worked well on one machine might work very poorly on others. In consequence of these observations, Lawson, Hanson, Kincaid and Krogh proposed a limited set of Basic Linear Algebra Subprograms (BLAS) to be (hopefully) optimized by hardware vendors, implemented in assembly language if necessary, that would form the basis of comprehensive linear algebra packages \cite{9}. These so-called Level 1 BLAS consisted of vector operations and some attendant co-routines. The first major package which used these BLAS kernels was LINPACK \cite{3}. Soon afterward, other major software libraries such as the IMSL library and NAG rewrote portions of their existing codes and structured new routines to use these BLAS. Early in their development, vector computers saw significant optimizations using the BLAS. Soon, however, such machines were clustered together in tight networks and somewhat larger kernels for numerical linear algebra were developed \cite{6,7} to include matrix-vector operations (Level 2 BLAS). Additionally, Fortran compilers were by then optimizing vector operations as efficiently as hand coded Level 1 BLAS. Subsequently, in the late 1980s, distributed memory machines were in production and shared memory machines began to have significant numbers of processors. A further set of matrix-matrix operations was proposed \cite{4} and soon standardized \cite{5} to form a Level 3. The first major package for linear algebra which used the Level 3 BLAS was LAPACK \cite{1} and subsequently a scalable (to large numbers of processors) version was released as ScaLAPACK \cite{2}. Vendors focused on Level 1, Level 2, and Level 3 BLAS which provided an easy route to optimizing LINPACK, then LAPACK. LAPACK not only integrated pre-existing solvers and eigenvalue routines found in EISPACK \cite{10} (which did not use the BLAS) and LINPACK (which used Level 1 BLAS), but incorporated the latest dense and banded linear algebra algorithms available. It also used the Level 3 BLAS which were optimized by much vendor effort. Later, we will illustrate several BLAS routines. Conventions for different BLAS are indicated by

- A root operation. For example, \texttt{axpy} for the operation

\begin{equation}
\mathbf{y} := a \cdot \mathbf{x} + \mathbf{y}
\end{equation}

- A prefix (or combination prefix) to indicate the datatype of the operands, for example \texttt{saxpy} for single precision \texttt{axpy} operation, or \texttt{isamax} for the index of the maximum absolute element in an array of type \texttt{single}. 

6.2. BLAS

- a suffix if there is some qualifier, for example $\text{cdotc}$ or $\text{cdotu}$ for conjugated or unconjugated complex dot product, respectively:

$$\text{cdotc}(n, x, 1, y, 1) = \sum_{i=0}^{n-1} x_i \bar{y}_i$$

$$\text{cdotu}(n, x, 1, y, 1) = \sum_{i=0}^{n-1} x_i y_i$$

where both $x, y$ are vectors of complex elements.

Tables 6.1 and 6.2 give the prefix/suffix and root combinations for the BLAS, respectively.

6.2.1 Typical performance numbers for the BLAS

Let us look at typical representations of all three levels of the BLAS, $\text{daxpy}$, $\text{ddot}$, $\text{dgemv}$, and $\text{dgemm}$, that perform some basic operations. Additionally, we look at the rank-1 update routine $\text{dger}$. An overview on the number of memory accesses and floating point operations is given in Table 6.3. The Level 1 BLAS comprise basic vector operations. A call of one of the Level 1 BLAS thus gives rise to $\mathcal{O}(n)$ floating point operations and $\mathcal{O}(n)$ memory accesses. Here, $n$ is the vector length. The Level 2 BLAS comprise operations that involve matrices and vectors. If the involved matrix is $n$-by-$n$ then both the memory accesses and the floating point operations are of $\mathcal{O}(n^2)$. In contrast, the Level 3 BLAS have a higher order of floating point operations than memory accesses. The most prominent operation of the Level 3 BLAS, matrix-matrix multiplication costs $\mathcal{O}(n^3)$ floating point operations while there are only $\mathcal{O}(n^2)$ reads and writes. The last column in Table 6.3 shows the crucial difference between the Level 3 BLAS and the rest.

Table 6.4 gives some performance numbers for the five BLAS of Table 6.3. Notice that the timer has a resolution of only 1 $\mu$sec! Therefore, the numbers in Table 6.4 have been obtained by timing a loop inside of which the respective function is called many times. The Mflop/s rates of the Level 1 BLAS $\text{ddot}$ and $\text{daxpy}$ quite precisely reflect the ratios of the memory accesses of the two routines, $2n$ vs. $3n$. The high rates are for vectors that can be held in the on-chip cache of 512 MB. The low 240 and 440 Mflop/s with the very long vectors are related to the memory bandwidth of about 1900 MB/s.

The Level 2 BLAS $\text{dgemm}$ has about the same performance as $\text{daxpy}$ if the matrix can be held in cache ($n = 100$). Otherwise it is considerably reduced. $\text{dger}$ has a high volume of read and write operations, while the number of floating point operations is limited.

Table 6.2: Summary of the Basic Linear Algebra Subroutines.
6.3. Blocking

This leads to a very low performance rate. The Level 3 BLAS \texttt{dgemm} performs at a good fraction of the peak performance of the processor (4.8\,Gflop/s). The performance increases with the problem size. We see from Table 6.3 that the ratio of computation to memory accesses increases with the problem size. This ratio is analogous to a volume to surface area effect.

Table 6.4: Some performance numbers for typical BLAS in Mflop/s for a 2.4 GHz Pentium 4.

6.3 Blocking

In the previous section we have seen that it is important to use Level 3 BLAS. However, in the algorithm we have treated so far, there were no blocks. For instance, in the reduction to Hessenberg form we applied Householder (elementary) reflectors from left and right to a matrix to introduce zeros in one of its columns.

The essential point here is to \emph{gather} a number of reflectors to a single block transformation. Let \( P_i = I - 2u_iu_i^* \), \( i = 1, 2, 3 \), be three Householder reflectors. Their product is

\[
P = P_3P_2P_1 = (I - 2u_3u_3^*)(I - 2u_2u_2^*)(I - 2u_1u_1^*)
\]

\[
= I - 2u_3u_3^* - 2u_2u_2^* - 2u_1u_1^* + 4u_3u_3^*u_2u_2^* + 4u_3u_3^*u_1u_1^* + 4u_2u_2^*u_1u_1^*
\]

\[
+ 8u_3u_3^*u_2u_2^*u_1u_1^*,
\]

\[
(6.2)
\]

So, if e.g. three rotations are to be applied on a matrix in blocked fashion, then the three Householder vectors \( u_1, u_2, u_3 \) have to be found first. To that end the rotations are first applied only on the first three columns of the matrix, see Fig. 6.1. Then, the blocked rotation is applied to the rest of the matrix.
Remark 6.1. Notice that a similar situation holds for Gaussian elimination because

\[
\begin{bmatrix}
1 & l_{21} & 1 \\
l_{31} & 1 \\
\vdots & \ddots & \ddots \\
l_{n1} & & 1
\end{bmatrix}
\begin{bmatrix}
1 \\
l_{32} & 1 \\
\vdots & \ddots & \ddots \\
l_{n2} & & 1
\end{bmatrix}
= 
\begin{bmatrix}
1 & l_{21} & 1 \\
l_{31} & l_{32} & 1 \\
\vdots & \vdots & \ddots \\
l_{n1} & l_{n2} & 1
\end{bmatrix}.
\]

However, things are complicated because of pivoting.

6.4 LAPACK solvers for the symmetric eigenproblems

To give a feeling how LAPACK is organized we consider solvers for the symmetric eigenproblem (SEP). Except for this problem there are driver routines for linear systems, least squares problems, nonsymmetric eigenvalue problems, the computation of the singular value decomposition (SVD).

The basic task of the symmetric eigenproblem routines is to compute values of \( \lambda \) and, optionally, corresponding vectors \( z \) for a given matrix \( A \).

There are four types of driver routines for symmetric and Hermitian eigenproblems. Originally LAPACK had just the simple and expert drivers described below, and the other two were added after improved algorithms were discovered. Ultimately we expect the algorithm in the most recent driver (called RRR below) to supersede all the others, but in LAPACK 3.0 the other drivers may still be faster on some problems, so we retain them.

- A simple driver computes all the eigenvalues and (optionally) eigenvectors.
- An expert driver computes all or a selected subset of the eigenvalues and (optionally) eigenvectors. If few enough eigenvalues or eigenvectors are desired, the expert driver is faster than the simple driver.
6.4. LAPACK SOLVERS FOR THE SYMMETRIC EIGENPROBLEMS

- A divide-and-conquer driver solves the same problem as the simple driver. It is much faster than the simple driver for large matrices, but uses more workspace. The name divide-and-conquer refers to the underlying algorithm.

- A relatively robust representation (RRR) driver computes all or (in a later release) a subset of the eigenvalues, and (optionally) eigenvectors. It is the fastest algorithm of all (except for a few cases), and uses the least workspace. The name RRR refers to the underlying algorithm.

This computation proceeds in the following stages:

1. The real symmetric or complex Hermitian matrix $A$ is reduced to real tridiagonal form $T$. If $A$ is real symmetric this decomposition is $A = QTQ^T$ with $Q$ orthogonal and $T$ symmetric tridiagonal. If $A$ is complex Hermitian, the decomposition is $A = QTQ^H$ with $Q$ unitary and $T$, as before, real symmetric tridiagonal.

2. Eigenvalues and eigenvectors of the real symmetric tridiagonal matrix $T$ are computed. If all eigenvalues and eigenvectors are computed, this is equivalent to factorizing $T$ as $T = SAS^T$, where $S$ is orthogonal and $A$ is diagonal. The diagonal entries of $A$ are the eigenvalues of $T$, which are also the eigenvalues of $A$, and the columns of $S$ are the eigenvectors of $T$; the eigenvectors of $A$ are the columns of $Z = QS$, so that $A = Z\Lambda Z^T$ ($Z\Lambda Z^H$ when $A$ is complex Hermitian).

In the real case, the decomposition $A = QTQ^T$ is computed by one of the routines _sytrd, _sptrd, or _sbtrd, depending on how the matrix is stored. The complex analogues of these routines are called _hetrd, _hptrd, and _hbtrd. The routine _sytrd (or _hetrd) represents the matrix $Q$ as a product of elementary reflectors. The routine _orgtr (or in the complex case _unmtr) is provided to form $Q$ explicitly; this is needed in particular before calling _steqr to compute all the eigenvectors of $A$ by the QR algorithm. The routine _ormtr (or in the complex case _unmtr) is provided to multiply another matrix by $Q$ without forming $Q$ explicitly; this can be used to transform eigenvectors of $T$ computed by _stein, back to eigenvectors of $A$.

For the names of the routines for packed and banded matrices, see [1].

There are several routines for computing eigenvalues and eigenvectors of $T$, to cover the cases of computing some or all of the eigenvalues, and some or all of the eigenvectors. In addition, some routines run faster in some computing environments or for some matrices than for others. Also, some routines are more accurate than other routines.

_ steqr This routine uses the implicitly shifted QR algorithm. It switches between the QR and QL variants in order to handle graded matrices. This routine is used to compute all the eigenvalues and eigenvectors.

_ sterf This routine uses a square-root free version of the QR algorithm, also switching between QR and QL variants, and can only compute all the eigenvalues. This routine is used to compute all the eigenvalues and no eigenvectors.

_ stedc This routine uses Cuppen’s divide and conquer algorithm to find the eigenvalues and the eigenvectors. _stedc can be many times faster than _steqr for large matrices but needs more work space ($2n^2$ or $3n^2$). This routine is used to compute all the eigenvalues and eigenvectors.

_ steqr This routine uses the relatively robust representation (RRR) algorithm to find eigenvalues and eigenvectors. This routine uses an $LDL^T$ factorization of a number of
CHAPTER 6. LAPACK AND THE BLAS

translates $T - \sigma I$ of $T$, for one shift $\sigma$ near each cluster of eigenvalues. For each translate the algorithm computes very accurate eigenpairs for the tiny eigenvalues. _steogr is faster than all the other routines except in a few cases, and uses the least workspace.

_stebz This routine uses bisection to compute some or all of the eigenvalues. Options provide for computing all the eigenvalues in a real interval or all the eigenvalues from the $i$th to the $j$th largest. It can be highly accurate, but may be adjusted to run faster if lower accuracy is acceptable.

_stein Given accurate eigenvalues, this routine uses inverse iteration to compute some or all of the eigenvectors.

6.5 Generalized Symmetric Definite Eigenproblems (GSEP)

Drivers are provided to compute all the eigenvalues and (optionally) the eigenvectors of the following types of problems:

1. $A z = \lambda B z$
2. $AB z = \lambda z$
3. $BA z = \lambda z$

where $A$ and $B$ are symmetric or Hermitian and $B$ is positive definite. For all these problems the eigenvalues $\lambda$ are real. The matrices $Z$ of computed eigenvectors satisfy $Z^T A Z = \Lambda$ (problem types 1 and 3) or $Z^{-1} A Z^{-T} = I$ (problem type 2), where $\Lambda$ is a diagonal matrix with the eigenvalues on the diagonal. $Z$ also satisfies $Z^T B Z = I$ (problem types 1 and 2) or $Z^T B Z = I$ (problem type 3).

There are three types of driver routines for generalized symmetric and Hermitian eigenproblems. Originally LAPACK had just the simple and expert drivers described below, and the other one was added after an improved algorithm was discovered.

- a simple driver computes all the eigenvalues and (optionally) eigenvectors.
- an expert driver computes all or a selected subset of the eigenvalues and (optionally) eigenvectors. If few enough eigenvalues or eigenvectors are desired, the expert driver is faster than the simple driver.
- a divide-and-conquer driver solves the same problem as the simple driver. It is much faster than the simple driver for large matrices, but uses more workspace. The name divide-and-conquer refers to the underlying algorithm.

6.6 An example of a LAPACK routines

The double precision subroutine dsysix.f implements the reduction to tridiagonal form. We give it here in full length.

SUBROUTINE DSYTRD( UPLO, N, A, LDA, D, E, TAU, WORK, LWORK, INFO )
* -- LAPACK routine (version 3.0) --
* Univ. of Tennessee, Univ. of California Berkeley, NAG Ltd.,
* Courant Institute, Argonne National Lab, and Rice University
* June 30, 1999
6.6. AN EXAMPLE OF A LAPACK ROUTINES

* .. Scalar Arguments ..
  CHARACTER UPLO
  INTEGER INFO, LDA, LWORK, N
* ..
* .. Array Arguments ..
  DOUBLE PRECISION A( LDA, * ), D( * ), E( * ), TAU( * ),
  WORK( * )
* *
* Purpose
* =======
* DSYTRD reduces a real symmetric matrix A to real symmetric
* tridiagonal form T by an orthogonal similarity transformation:
* Q**T * A * Q = T.
* *
* Arguments
* =========
* UPLO (input) CHARACTER*1
  = 'U': Upper triangle of A is stored;
  = 'L': Lower triangle of A is stored.
* *
* N (input) INTEGER
  The order of the matrix A. N >= 0.
* *
* A (input/output) DOUBLE PRECISION array, dimension (LDA,N)
  On entry, the symmetric matrix A. If UPLO = 'U', the leading
  N-by-N upper triangular part of A contains the upper
  triangular part of the matrix A, and the strictly lower
  triangular part of A is not referenced. If UPLO = 'L', the
  leading N-by-N lower triangular part of A contains the lower
  triangular part of the matrix A, and the strictly upper
  triangular part of A is not referenced.
  On exit, if UPLO = 'U', the diagonal and first superdiagonal
  of A are overwritten by the corresponding elements of the
  tridiagonal matrix T, and the elements above the first
  superdiagonal, with the array TAU, represent the orthogonal
  matrix Q as a product of elementary reflectors; if UPLO
  = 'L', the diagonal and first subdiagonal of A are over-
  written by the corresponding elements of the tridiagonal
  matrix T, and the elements below the first subdiagonal, with
  the array TAU, represent the orthogonal matrix Q as a product
  of elementary reflectors. See Further Details.
* *
* LDA (input) INTEGER
  The leading dimension of the array A. LDA >= max(1,N).
* *
* D (output) DOUBLE PRECISION array, dimension (N)
  The diagonal elements of the tridiagonal matrix T:
  D(i) = A(i,i).
* *
* E (output) DOUBLE PRECISION array, dimension (N-1)
  The off-diagonal elements of the tridiagonal matrix T:
  E(i) = A(i,i+1) if UPLO = 'U', E(i) = A(i+1,i) if UPLO = 'L'.
* *
* TAU (output) DOUBLE PRECISION array, dimension (N-1)
  The scalar factors of the elementary reflectors (see Further
  Details).
WORK (workspace/output) DOUBLE PRECISION array, dimension (LWORK)
On exit, if INFO = 0, WORK(1) returns the optimal LWORK.

LWORK (input) INTEGER
The dimension of the array WORK. LWORK >= 1.
For optimum performance LWORK >= N*NB, where NB is the
optimal blocksize.

If LWORK = -1, then a workspace query is assumed; the routine
only calculates the optimal size of the WORK array, returns
this value as the first entry of the WORK array, and no error
message related to LWORK is issued by XERBLA.

INFO (output) INTEGER
= 0: successful exit
< 0: if INFO = -i, the i-th argument had an illegal value

Further Details

If UPLO = 'U', the matrix Q is represented as a product of elementary
reflectors

\[ Q = H(n-1) \ldots H(2) H(1) \]

Each H(i) has the form

\[ H(i) = I - \tau v v' \]

where \( \tau \) is a real scalar, and \( v \) is a real vector with
\( v(i+1:n) = 0 \) and \( v(i) = 1 \); \( v(1:i-1) \) is stored on exit in
\( A(1:i-1,i+1) \), and \( \tau \) in TAU(i).

If UPLO = 'L', the matrix Q is represented as a product of elementary
reflectors

\[ Q = H(1) H(2) \ldots H(n-1) \]

Each H(i) has the form

\[ H(i) = I - \tau v v' \]

where \( \tau \) is a real scalar, and \( v \) is a real vector with
\( v(1:i) = 0 \) and \( v(i+1) = 1 \); \( v(i+2:n) \) is stored on exit in \( A(i+2:n,i) \),
and \( \tau \) in TAU(i).

The contents of \( A \) on exit are illustrated by the following examples
with \( n = 5 \):

if UPLO = 'U': if UPLO = 'L':

\[
\begin{pmatrix}
  d & e & v_2 & v_3 & v_4 \\
  d & e & v_3 & v_4 & \\
  & d & e & v_4 & \\
  & & d & e & v_1 \\
  & & & d & v_1 v_2 v_3 e d
\end{pmatrix}
\]

where \( d \) and \( e \) denote diagonal and off-diagonal elements of \( T \), and \( v_i \)
denotes an element of the vector defining \( H(i) \).

END

Notice that most of the lines (indicated by ‘∗’) contain comments. The initial comment
lines also serve as manual pages. Notice that the code only looks at one half (upper or
lower triangle) of the symmetric input matrix. The other triangle is used to store the
Householder vectors. These are normed such that the first component is one,

\[
I - 2uu^* = I - 2|u_1|^2(u/u_1)(u/u_1)^* = I - \tau vv^*.
\]

In the main loop of dsytrd there is a call to a subroutine dlatrd that generates a
block reflector. (The blocksize is NB.) Then the block reflector is applied by the routine
dsyr2k.

Directly after the loop there is a call to the ‘unblocked dsytrd’ named dsytd2 to deal with the first/last few (<NB) rows/columns of the matrix. This excerpt concerns the situation when the upper triangle of the matrix $A$ is stored. In that routine the mentioned loop looks very much the way we derived the formulae.

```

Bibliography

Chapter 7

Vector iteration (power method)

7.1 Simple vector iteration

In this chapter we consider the simplest method to compute a single extremal eigenvalue, called vector iteration or power method \[2, 5\]. Let \( A \in \mathbb{F}^{n \times n} \). Starting with an arbitrary initial vector \( x^{(0)} \in \mathbb{F}^n \) we form the vector sequence \( \{x^{(k)}\}_{k=0}^{\infty} \) by defining

\[
x^{(k)} := Ax^{(k-1)}, \quad k = 1, 2, \ldots
\]

Clearly,

\[
x^{(k)} := A^k x^{(0)}.
\]

The hope is that the \( x^{(k)} \) converge to an eigenvector associated with the eigenvalue of largest magnitude. As we are interested only in the direction but not in the length of the eigenvector, there is no need to normalize the iterates in (7.1), well at least in theory. In practice, \( x^{(k)} \) may either underflow (if \( \|A\| < 1 \)) or overflow (if \( \|A\| > 1 \)) for large \( k \). Thus, one usually adds a normalization step to (7.1), leading to Algorithm 7.1.

Algorithm 7.1 Simple vector iteration (power method)

1: Choose a starting vector \( x^{(0)} \in \mathbb{F}^n \) with \( \|x^{(0)}\| = 1 \).
2: \( k = 0 \).
3: repeat
4: \( k := k + 1 \);
5: \( y^{(k)} := Ax^{(k-1)} \);
6: \( \mu_k := \|y^{(k)}\| \);
7: \( x^{(k)} := y^{(k)}/\mu_k \);
8: until a convergence criterion is satisfied

The vectors \( x^{(k)} \) generated by Algorithm 7.1 have all norm (length) one. That is, \( \{x^{(k)}\}_{k=0}^{\infty} \) is a sequence on the unit sphere in \( \mathbb{F}^n \).

Let \( A = X J Y^* \) be the Jordan normal form of \( A \) with \( Y^* := X^{-1} \), see Section 2.8.

Then,

\[
Y^* x^{(k)} := J Y^* x^{(k-1)} \quad \text{and} \quad Y^* x^{(k)} := J^k Y^* x^{(0)},
\]

respectively. If the sequence \( \{x^{(k)}\}_{k=0}^{\infty} \) converges to \( x_* \) then the sequence \( \{y^{(k)}\}_{k=0}^{\infty} \) with \( y^{(k)} = Y^* x^{(k)} \) converges to \( y_* = Y^* x_* \). By consequence, for the convergence analysis, we may assume without loss of generality (w.l.o.g.) that \( A \) is a Jordan block matrix.
7.2 Angles between vectors

Let $\mathbf{q}_1$ and $\mathbf{q}_2$ be unit vectors, cf. Fig. 7.1. The length of the orthogonal projection of $\mathbf{q}_2$ on $\text{span}\{\mathbf{q}_1\}$ is given by

\begin{equation}
(7.4) \quad c := \|\mathbf{q}_1 \mathbf{q}_1^* \mathbf{q}_2\| = |\mathbf{q}_1^* \mathbf{q}_2| \leq 1.
\end{equation}

The length of the orthogonal projection of $\mathbf{q}_2$ on $\text{span}\{\mathbf{q}_1\}^\perp$ is

\begin{equation}
(7.5) \quad s := \|\left(\mathbf{I} - \mathbf{q}_1 \mathbf{q}_1^*\right) \mathbf{q}_2\|.
\end{equation}

As $\mathbf{q}_1 \mathbf{q}_1^*$ is an orthogonal projection we have by Pythagoras’ formula that

\begin{equation}
(7.6) \quad 1 = \|\mathbf{q}_2\|^2 = \|\mathbf{q}_1 \mathbf{q}_1^* \mathbf{q}_2\|^2 + \|\left(\mathbf{I} - \mathbf{q}_1 \mathbf{q}_1^*\right) \mathbf{q}_2\|^2 = s^2 + c^2.
\end{equation}

Alternatively, we can conclude from (7.5) that

\begin{equation}
(7.7) \quad s^2 = \|\left(\mathbf{I} - \mathbf{q}_1 \mathbf{q}_1^*\right) \mathbf{q}_2\|^2 = \mathbf{q}_2^* \left(\mathbf{I} - \mathbf{q}_1 \mathbf{q}_1^*\right) \mathbf{q}_2 = \mathbf{q}_2^* \mathbf{q}_2 - (\mathbf{q}_2^* \mathbf{q}_1)(\mathbf{q}_1^* \mathbf{q}_2) = 1 - c^2.
\end{equation}

So, there is a number, say, $\vartheta$, $0 \leq \vartheta \leq \frac{\pi}{2}$, such that $c = \cos \vartheta$ and $s = \sin \vartheta$. We call this uniquely determined number $\vartheta$ the angle between the vectors $\mathbf{q}_1$ and $\mathbf{q}_2$:

$$\vartheta = \angle(\mathbf{q}_1, \mathbf{q}_2).$$

The generalization to arbitrary vectors is straightforward.

**Definition 7.1** The angle $\theta$ between two nonzero vectors $\mathbf{x}$ and $\mathbf{y}$ is given by

\begin{equation}
(7.8) \quad \theta = \angle(\mathbf{x}, \mathbf{y}) = \arcsin\left(\left\|\left(I - \frac{\mathbf{x} \mathbf{x}^*}{\|\mathbf{x}\|^2}\right) \frac{\mathbf{y}}{\|\mathbf{y}\|}\right\|\right) = \arccos\left(\frac{\mathbf{x}^* \mathbf{y}}{\|\mathbf{x}\| \|\mathbf{y}\|}\right).
\end{equation}

When investigating the convergence behaviour of eigensolvers we usually show that the angle between the approximating and the desired vector tends to zero as the number of iterations increases. In fact it is more convenient to work with the sine of the angle.
7.3. CONVERGENCE ANALYSIS

In the formulae above we used the projections $P$ and $I-P$ with $P = q_1q_1^*$. We would have arrived at the same point if we had exchanged the roles of $q_1$ and $q_2$. As
\[
\|q_1q_1^*q_2\| = \|q_2q_2^*q_1\| = \|q_2^*q_1\|
\]
we get
\[
\|(I - q_1^*)q_2\| = \|(I - q_2^*)q_1\|.
\]
This immediately leads to

Lemma 7.2 \quad \sin \angle(q_1, q_2) = \|q_1q_1^* - q_2q_2^*\|.

7.3 Convergence analysis

Let us now assume that $A$ has Jordan block form,
\[
(7.9) \quad A = \begin{bmatrix} \lambda_1 & 0^* \\ 0 & J_2 \end{bmatrix}
\]
with eigenvalues
\[
(7.10) \quad |\lambda_1| > |\lambda_2| \geq |\lambda_3| \geq \cdots \geq |\lambda_n|.
\]
Then, the eigenvector of $A$ corresponding to its largest eigenvalue $\lambda_1$ is $e_1$. We will now show that the iterates $x^{(k)}$ converge to $e_1$. More precisely, we will show that the angle $\angle(x^{(k)}, e_1)$ between $x^{(k)}$ and $e_1$ goes to zero with $k \to \infty$. Let
\[
x^{(k)} = \begin{pmatrix} x_1^{(k)} \\ x_2^{(k)} \\ \vdots \\ x_n^{(k)} \end{pmatrix} = : \begin{pmatrix} x_1^{(k)} \\ x_2^{(k)} \end{pmatrix}
\]
with $\|x^{(k)}\| = 1$. Then,
\[
\sin \vartheta^{(k)} := \sin(\angle(x^{(k)}, e_1)) = \|(I - e_1e_1^*)x^{(k)}\| = \|x_2^{(k)}\| = \sqrt{\sum_{i=2}^{n} |x_i^{(k)}|^2}.
\]
If we omit the normalization $\|x^{(k)}\| = 1$, which we will do for convenience, then this becomes
\[
\sin \vartheta^{(k)} := \sin(\angle(x^{(k)}, e_1)) = \frac{\|x_2^{(k)}\|}{\|x^{(k)}\|} = \sqrt{\frac{\sum_{i=2}^{n} |x_i^{(k)}|^2}{\sum_{i=1}^{n} |x_i^{(k)}|^2}}.
\]
This means that for the convergence analysis we look at the iteration (7.1), while the actual implementation follows closely Algorithm 7.1.

From (7.1) we have
\[
x^{(k)} = \begin{pmatrix} x_1^{(k)} \\ x_2^{(k)} \end{pmatrix} = \begin{bmatrix} \lambda_1 & 0^* \\ 0 & J_2 \end{bmatrix} \begin{pmatrix} x_1^{(k-1)} \\ x_2^{(k-1)} \end{pmatrix} = \begin{bmatrix} \lambda_1 & 0^* \\ 0 & J_2 \end{bmatrix}^k \begin{pmatrix} x_1^{(0)} \\ x_2^{(0)} \end{pmatrix}.
\]
CHAPTER 7. VECTOR ITERATION (POWER METHOD)

Defining

\[(7.11) \quad y^{(k)} := \frac{1}{\lambda_2^k} x^{(k)}\]

we have

\[y^{(k)} = \begin{bmatrix} 1 & 0^* \\ 0 & \frac{1}{\lambda_1} J_2 \end{bmatrix} y^{(k-1)}.\]

Let us assume that \(y_1^{(0)} = 1\). Then \(y_1^{(k)} = 1\) for all \(k\) and

\[y_2^{(k)} = \frac{1}{\lambda_1} J_2 y_2^{(k-1)}, \quad \frac{1}{\lambda_1} J_2 = \begin{bmatrix} \mu_2 & * & * \\ & \mu_3 & * \\ & & \ddots & * \\ & & & \mu_{n-1} \end{bmatrix}, \quad |\mu_k| = \frac{|\lambda_k|}{|\lambda_1|} < 1.\]

For the sequel we need

**Theorem 7.3** Let \(||\cdot||\) be any matrix norm. Then

\[(7.12) \quad \lim_{k \to \infty} ||M^k||^{1/k} = \rho(M) = \max_i |\lambda_i(M)|.\]

**Proof.** See Horn-Johnson [3], pp.297-299.

**Definition 7.4** \(\rho(M)\) in \((7.12)\) is call spectral radius of \(M\).

Regarding the convergence of the vector iteration, **Theorem 7.3** implies that for any \(\varepsilon > 0\) there is an integer \(K(\varepsilon)\) such that

\[(7.13) \quad ||M^k||^{1/k} \leq \rho(M) + \varepsilon, \quad \forall k > K(\varepsilon).\]

We will apply this theorem to the case \(M = \lambda_1^{-1} J_2\), the matrix norm \(||\cdot||\) will be the ordinary 2-norm. Thus, for any \(\varepsilon > 0\) there is a \(K(\varepsilon) \in \mathbb{N}\) with

\[(7.14) \quad \left\| \left( \frac{1}{\lambda_1} J_2 \right)^k \right\|^{1/k} \leq |\mu_2| + \varepsilon, \quad \forall k > K(\varepsilon).\]

We can choose \(\varepsilon\) such that

\[|\mu_2| + \varepsilon < 1.\]

Then,

\[\sin(\angle(y^{(k)}, e_1)) = \frac{||(I - e_1 e_1^*) y^{(k)}||}{\|y^{(k)}\|} = \frac{\|y_2^{(k)}\|}{\|y^{(k)}\|} = \frac{\|y_2^{(k)}\|}{\sqrt{1 + \|y_2^{(k)}\|^2}} \leq \|y_2^{(k)}\| \leq \|\frac{1}{\lambda_1} J_2^k\| \|y_2^{(0)}\| \leq (|\mu_2| + \varepsilon) \|y_2^{(0)}\|.\]

Thus, the angle between \(y^{(k)}\) and \(e_1\) goes to zero with a rate \(\mu_2 + \varepsilon\) for any positive \(\varepsilon\). Since \(x^{(k)}\) is a scalar multiple of \(y^{(k)}\) the same holds for the angle between \(x^{(k)}\) and \(e_1\). Since we can choose \(\varepsilon\) arbitrarily small, we have proved that

\[\sin \phi^{(k)} = \sin(\angle(x^{(k)}, u_1)) \leq c \cdot \frac{\lambda_2}{|\lambda_1|}^k\]
7.3. CONVERGENCE ANALYSIS

provided that $x_1^{(0)} = e_1^* x^{(0)} \neq 0$.

Returning to a general matrix $A \in \mathbb{F}^{n \times n}$ with Jordan normal form $A = X J Y^*$, we employ equation (7.3). The sequence $y^{(k)} = Y^* x^{(k)}$ converges to $y_* = \alpha e_1$ with $\alpha \neq 0$. Therefore, $x^{(k)}$ converges to a multiple of $X e_1$, which is an eigenvector associated with the largest eigenvalue $\lambda_1$. The condition $e_1^* y^{(0)} \neq 0$ translates into

$$e_1^* (Y^* x^{(0)}) = (Y e_1)^* x^{(0)} \neq 0.$$ 

The first column of $Y$ is a left eigenvector associated with $\lambda_1$. Therefore, we have proved

**Theorem 7.5** Let the eigenvalues of $A \in \mathbb{F}^{n \times n}$ be arranged such that $|\lambda_1| > |\lambda_3| \geq \cdots \geq |\lambda_n|$. Let $u_1$ and $v_1$ be right and left eigenvectors of $A$ corresponding to $\lambda_1$, respectively. Then, the vector sequence generated by Algorithm 7.1 converges to $u_1$ in the sense that

$$(7.15) \quad \sin \theta^{(k)} = \sin(\angle(x^{(k)}, u_1)) \leq c \cdot \frac{|\lambda_2|}{|\lambda_1|} k$$

provided that $v_1^* x^{(0)} \neq 0$. \hfill \qed

**Remark 7.1.** The quantity $\mu_k$ in Algorithm 7.1 converges to $|\lambda_1|$. The true value $\lambda_1 \in \mathbb{C}$ can be found by comparing single components of $y^{(k)}$ and $x^{(k-1)}$. If $\lambda_1 \in \mathbb{R}$ then only the sign of $\lambda_1$ is at stake. \hfill \qed

**Remark 7.2.** The convergence of the vector iteration is faster the smaller the quotient $|\lambda_2|/|\lambda_1|$ is. \hfill \qed

**Remark 7.3.** From (7.12) we see that the norm of the powers of a matrix goes to zero if all eigenvalues are smaller than one in modulus. For small powers the norm can initially grow considerably. In Fig. 7.2 we have plotted the norms of $B^k$ with

$$(7.16) \quad B = \begin{bmatrix} 0.9 & 5 \\ 0 & 0.9 \end{bmatrix}.$$
Chapter 7. Vector Iteration (Power Method)

Remark 7.4. If $v_1^*x^{(0)} = 0$ then the vector iteration converges to an eigenvector corresponding to the second largest eigenvalue. In practice, rounding errors usually prevent this behaviour of the algorithm. After a long initial phase the $x^{(k)}$ turn to $u_1$.

Remark 7.5. In case that $\lambda_1 \neq \lambda_2$ but $|\lambda_1| = |\lambda_2|$ there may be no convergence at all. An example is

$$A = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad x^{(0)} = \begin{bmatrix} \alpha \\ \beta \end{bmatrix}. $$

7.4 A numerical example

In the following MATLAB script we assume that $A$ is upper triangular and that the largest eigenvalue (in modulus) is at position $(1,1)$, i.e., $|a_{1,1}| > |a_{j,j}|$ for all $j > 1$.

```matlab
% Demo Simple Vector Iteration

n = 6;
randn('state',0);
A = diag([n:-1:1]) + triu(randn(n),1) % upper triangular matrix
x0 = rand(n,1); x0=x0/norm(x0) % initial vector

e = eye(n,1); % Right eigenvector corresponding to largest
% eigenvalue $A(1,1)$

x=x0; ang = norm(x - e*(e'*x))
hist = [ang,nan,nan];
if ~exist('tol'), tol = 100*eps; end
oldang = nan;
while ang > tol
    x = A*x;
    mue = norm(x); % This is an approximation for the
    x = x/mue; % searched eigenvalue
    ang = norm(x - e*(e'*x));
    hist = [hist; [mue,ang,ang/oldang]];
    oldang = ang;
end

Because the solution is known, we can compute the angle between iterate and true solution. We can even use this angle in the stopping criterion. The matrix $A$ is given by

$$A = 
\begin{bmatrix}
6.0000 & 1.1892 & -0.5883 & -0.0956 & -0.6918 & -0.3999 \\
0 & 5.0000 & 2.1832 & -0.8323 & 0.8580 & 0.6900 \\
0 & 0 & 4.0000 & 0.2944 & 1.2540 & 0.8156
\end{bmatrix}$$
7.5. THE SYMMETRIC CASE

Let us now consider the Hermitian/symmetric case. We again assume the now real eigenvalues to be arranged as in (7.10). But now the Schur decomposition of $A$ becomes its spectral decomposition,

$$ A = U \Lambda U^*, \quad U = [u_1, \ldots, u_n], \quad \Lambda = \text{diag}(\lambda_1, \ldots, \lambda_n). $$

For the convergence analysis, we assume that $A$ is diagonal, and that

$$ \lambda_1 > \lambda_2 \geq \cdots \geq \lambda_n \geq 0. $$

Therefore, in (7.9) we have $J_2 = \text{diag}(\lambda_2, \ldots, \lambda_n)$, i.e., all Jordan blocks are $1 \times 1$.

In contrast to the general case, in the Hermitian case we approximate the eigenvalue by the Rayleigh quotient of $x^{(k)}$,

$$ \lambda^{(k)} := x^{(k)^*} A x^{(k)}, \quad \|x^{(k)}\| = 1. $$

The symmetric algorithm is given in Algorithm 7.2.
Figure 7.4: Plot of three important quantities: eigenvalue, angle between eigenvector approximation and exact eigenvector, convergence rate of eigenvector. Here, the initial vector is chosen orthogonal to the left eigenvector corresponding to the largest eigenvalue.

Algorithm 7.2 Simple vector iteration for Hermitian matrices

1: Choose a starting vector $x^{(0)} \in \mathbb{F}^n$ with $\|x^{(0)}\| = 1$.
2: $y^{(0)} := Ax^{(0)}$.
3: $\lambda^{(0)} := y^{(0)*}x^{(0)}$.
4: $k := 0$.
5: while $\|y^{(k)} - \lambda^{(k)}x^{(k)}\| > \text{tol}$ do
6: $k := k + 1$;
7: $x^{(k)} := y^{(k-1)}/\|y^{(k-1)}\|$;
8: $y^{(k)} := Ax^{(k)}$;
9: $\lambda^{(k)} := y^{(k)*}x^{(k)}$;
10: end while

In order to investigate the convergence of the Rayleigh quotient we work with auxiliary vectors

\[
y^{(k)} = \begin{pmatrix} 1 \\ y_2^{(k)} \end{pmatrix} = \frac{1}{|x_1^{(k)}|}x^{(k)}.
\]

Notice, that any ‘reasonable’ approximation of the first eigenvector $e_1$ has a nonzero first component. For the Rayleigh quotients we have

\[
\rho(y^{(k)}) = \rho(x^{(k)}).
\]

Now,

\[
\lambda^{(k)} = \frac{y^{(k)*}Ay^{(k)}}{y^{(k)*}y^{(k)}} = \frac{(e_1 + y_2^{(k)})^*A(e_1 + y_2^{(k)})}{1 + \|y_2^{(k)}\|^2} = \frac{\lambda_1 + y_2^{(k)*}Ay_2^{(k)}}{1 + \|y_2^{(k)}\|^2}
\]
7.5. THE SYMMETRIC CASE

where we used that \( e_1^* y_2^{(k)} = 0 \) and \( e_1^* A y_2^{(k)} = 0 \). Because,

\[
\tan \vartheta^{(k)} := \tan(\angle(y^{(k)}, e_1)) = \| y_2^{(k)} \|
\]

and

\[
1 + \tan^2(\varphi) = \frac{1}{1 - \sin^2(\varphi)}
\]

we get from (7.21) that

\[
\lambda^{(k)} = (\lambda_1 + y_2^{(k)} A y_2^{(k)})(1 - \sin^2 \vartheta^{(k)}) = \lambda_1 - \lambda_1 \sin^2 \vartheta^{(k)} + y_2^{(k)} A y_2^{(k)} \cos^2 \vartheta^{(k)}.
\]

Now, since \( \lambda_1 > 0 \),

\[
0 \leq \lambda_1 - \lambda^{(k)} = \lambda_1 \sin^2 \vartheta^{(k)} - y_2^{(k)} A y_2^{(k)} \cos^2 \vartheta^{(k)} \\
\leq \lambda_1 \sin^2 \vartheta^{(k)} - \lambda_n \| y_2^{(k)} \|^2 \cos^2 \vartheta^{(k)} = (\lambda_1 - \lambda_n) \sin^2 \vartheta^{(k)}.
\]

In summary, we have proved

**Theorem 7.6** Let \( A \) be a symmetric matrix with spectral decomposition (7.17)–(7.18). Then, the simple vector iteration of Algorithm 7.2 computes sequences \( \{\lambda^{(k)}\}_{k=0}^\infty \) and \( \{x^{(k)}\}_{k=0}^\infty \) that converge linearly towards the largest eigenvalue \( \lambda_1 \) of \( A \) and the corresponding eigenvector \( u_1 \) provided that the initial vector \( x^{(0)} \) has a nonzero component in the direction of \( u_1 \), i.e., that \( u_1^T x^{(0)} \neq 0 \). The convergence rates are given by

\[
\sin \vartheta^{(k)} \leq \left| \frac{\lambda_2}{\lambda_1} \right|^k \sin \vartheta^{(0)}, \quad |\lambda_1 - \lambda^{(k)}| \leq (\lambda_1 - \lambda_n) \left| \frac{\lambda_2}{\lambda_1} \right|^{2k} \sin^2 \vartheta^{(0)}.
\]

where \( \vartheta^{(k)} = \angle(x^{(k)}, u_1) \).

Thus, the speed of convergence is determined by the ratio of the two eigenvalues largest in modulus and the quality of the initial guess \( x^{(0)} \). Both sequences \( \{\lambda^{(k)}\} \) and \( \{x^{(k)}\} \) converge linearly, but the decisive ratio appears squared in the bound for the approximation error in the eigenvalue. \( \lambda_1 - \lambda_n \) is called the **spread** of the spectrum of \( A \). Its occurrence in the bound for \( \lambda_{\text{max}} - \lambda^{(k)} \) shows that a simple scaling of the matrix does not affect the convergence behavior of the algorithm.

**Example 7.7** Let’s compute the smallest eigenvalue and corresponding eigenvector of the one-dimensional Poisson matrix \( T = T_n \) of Example 2.7 with \( n = 40 \). Let us assume that we know an upper bound \( \tau \) for the largest eigenvalue \( \lambda_n \) of \( T \) then the transformed matrix \( \tau I - T \) has the same eigenvectors as \( T \) and eigenvalues \( \tau - \lambda_n < \tau - \lambda_{n-1} < \cdots < \tau - \lambda_1 \).

So, we apply vector iteration to compute the desired quantities.

We set \( \tau = 4(n + 1)^2/\pi^2 \) a number that is easily obtained by applying Gerschgorin’s circle theorem. We performed a MATLAB experiment starting with a random vector.

```matlab
>> n=40;
>> T = (4*((n+1)^2/pi^2))*eye(n) - ((n+1)^2/pi^2)*p_1d(n);
>> rand('state',0); x0=rand(n,1);
>> [x, lam, nit]=vit(T,x0,1e-4);
>> tau-lam
ans =
    0.9995
>> nit
nit = 1968
```
In as many as 1968 iteration steps we arrived at an eigenvalue approximation 0.9995. This number is correct to all digits. The difference to the eigenvalue 1 of the continuous eigenvalue problem $-u''(x) = \lambda u(x)$ is due to the discretization error. Figure 7.5 shows the convergence history of this calculation. The straight lines show the actual angle $\vartheta^{(k)}$ between $x^{(k)}$ and $u_1$ (above) and the actual error $\lambda^{(k)} - \lambda_1$. These quantities can of course not be computed in general. In this example we know them, see Ex. 2.7. The dotted lines show powers of $q = (\tau - \lambda_2)/ (\tau - \lambda_1)$ that indicate the convergence rates given by Theorem 7.6. Here, $q = 0.9956$. Clearly, the convergence is as predicted.

Example 7.8 We mentioned that a good initial vector can reduce the number of iteration steps. Remember that the smallest eigenfunction is $\sin x$, a function that is positive on the whole interval $(0, \pi)$. Let us therefore set $x^{(0)}$ to be the vector of all ones.

```matlab
>> x0 = ones(n,1);
>> [x, lam, nit] = vit(T, x0, 1e-4);
>> nit
nit =
     866
```

This is a surprisingly high reduction in the number of iteration steps. Figure 7.6 shows the convergence history of this calculation. Again the dotted lines indicate the convergence rates that are to be expected. The actual convergence rates are evidently much better. How can that be?

The eigenvectors of $T_n$ resemble the eigenfunctions $\sin kx$ of the continuous eigenvalue problem. Therefore the coefficients corresponding to eigenvectors corresponding to eigenfunctions antisymmetric with respect to the point $\pi/2$ vanish. In particular $x_2 = 0$. Therefore the convergence rate is not $q = (\tau - \lambda_2)/(\tau - \lambda_1)$ but $\hat{q} = (\tau - \lambda_3)/(\tau - \lambda_1)$. This is verified by the numbers given in Fig. 7.7 where the asymptotic corrected convergence rates $q$ and $\hat{q}$ are indicated.
7.6. INVERSE VECTOR ITERATION

When computing the smallest eigenvalue of $T_n$ by the simple vector iteration we can find a better shift than $\tau$ above if the extremal points of the spectrum are known. Determine $\sigma$ such that $\sigma I_n - T_n$ exhibits the optimal convergence rate. Hint: On the one hand we would like the quotient $(\sigma - \lambda_{n-1})/(\sigma - \lambda_n)$ to be as small as possible. On the other hand $|\sigma - \lambda_1|/(\sigma - \lambda_n)$ must not become too big. Hint: Equate the two quantities.

7.6 Inverse vector iteration

The previous examples have shown that the convergence of simple vector iteration is potentially very slow. The quotient of the second largest to the largest eigenvalue are very close to 1. We noticed this by means of a very simple and small eigenvalue problem. The situation gets much worse if the problems are big.

We have seen in (2.28) that a polynomial in $A$ has the same eigenvectors as $A$. We therefore may try to find a polynomial that enhances the eigenvalue that we are looking for. This approach is however not successful in the most critical case when the wanted eigenvalue is very close to unwanted. In this situation, the shift-and-invert spectral transformation is most appropriate. Instead of a polynomial we transform the matrix by the rational function $f(\lambda) = 1/(\lambda - \sigma)$ where $\sigma$ is a so-called shift that is chosen close to the desired eigenvalue. Simple vector iteration with the matrix $(A - \sigma I)^{-1}$ is referred to as inverse vector iteration, see Algorithm 7.6.

\begin{equation}
\tag{7.24}
x^{(k)} := (A - \sigma I)^{-1} x^{(k-1)} \iff (A - \sigma I) x^{(k)} := x^{(k-1)}, \quad k = 1, 2, \ldots
\end{equation}

The iteration converges towards the eigenvector with eigenvalue closest to $\sigma$. A linear system of equations has to be solved in each iteration step. Of course only one Cholesky or LU factorization has to be computed as the shift remains constant in all iterations. The stopping criterion is changed into

\begin{equation}
\tag{7.25}
\|x^{(k)} - y^{(k)}/\mu^{(k)}\| \leq \text{tol}\|y^{(k)}\|
\end{equation}
CHAPTER 7. VECTOR ITERATION (POWER METHOD)

Figure 7.7: Simple vector iteration with $\tau I_{40} - T_{30}$ and starting vector $(1, 1, \ldots, 1)^T$

Algorithm 7.3 Inverse vector iteration

1: Choose a starting vector $x_0 \in \mathbb{R}^n$ and a shift $\sigma$.
2: Compute the LU factorization of $A - \sigma I$: $LU = P(A - \sigma I)$
3: $y(0) := U^{-1}L^{-1}P^{(0)}x^{(0)}$, $\mu(0) = y^{(0)} \cdot x^{(0)}$, $\lambda(0) := \sigma + 1/\mu(0)$, $k := 0$.
4: while $\|x^{(k)} - y^{(k)} / \mu^{(k)}\| > \text{tol}\|y^{(k)}\|$ do
5: $k := k + 1$.
6: $x^{(k)} := y_{k-1} / \|y_{k-1}\|$.
7: $y^{(k)} := U^{-1}L^{-1}P^{(k)}x^{(k)}$.
8: $\mu^{(k)} := y^{(k)} \cdot x^{(k)}$, $\lambda^{(k)} := \sigma + 1/\mu^{(k)}$.
9: end while

where we have used

$$A x^{(k)} - \lambda^{(k)} y^{(k)} = A y^{(k)} - \left(\sigma - \frac{1}{\mu^{(k)}}\right) y^{(k)} = x^{(k)} - y^{(k)} / \mu^{(k)}$$

The convergence result of Theorem 7.6 can easily be adapted to the new situation if it is taken into account that $A - \sigma I$ has eigenpairs $(\mu_i, u_i)$ with $\mu_i = 1 / (\sigma - \lambda_i)$.

Theorem 7.10 Let $A$ be symmetric positive definite with spectral decomposition (7.17). Let $\lambda_1, \ldots, \lambda_n$ be a renumeration of the eigenvalues in (7.17) such that

$$\frac{1}{|\lambda_1 - \sigma|} > \frac{1}{|\lambda_2 - \sigma|} \geq \cdots \geq \frac{1}{|\lambda_n - \sigma|}$$

Then, provided that $\mathbf{u}_1^* x^{(0)} \neq 0$, the inverse vector iteration of Algorithm 7.6 constructs sequences $\{\lambda^{(k)}\}_{k=0}^{\infty}$ and $\{x^{(k)}\}_{k=0}^{\infty}$ that converge linearly towards that eigenvalue $\lambda_1$ closest to the shift $\sigma$ and to the corresponding eigenvector $\mathbf{u}_1$, respectively. The bounds

$$\sin \hat{\theta}^{(k)} \leq \left|\frac{\lambda_1 - \sigma}{\lambda_2 - \sigma}\right|^k \sin \theta^{(0)}$$

$$\lambda^{(k)} - \lambda_1 \leq \delta \left|\frac{\lambda_1 - \sigma}{\lambda_2 - \sigma}\right|^{2k} \sin^2 \theta^{(0)}$$

hold with $\theta^{(k)} = \angle(x^{(k)}, \mathbf{u}_1)$ and $\delta = \text{spread}(\sigma((A - \sigma I)^{-1}))$. 

$\blacksquare$
If the shift $\sigma$ approximates very well an eigenvalue of $A$ then $\frac{\lambda^{(k)} - \sigma}{\lambda_n - \sigma} \ll 1$ and convergence is very rapid.

**Example 7.11** Let us now use inverse iteration to compute the smallest eigenvalue and corresponding eigenvector of the one-dimensional Poisson matrix $T = T_n$ of Example 2.7 with $n = 40$. If we assume that we know that the smallest eigenvalue $\lambda_1$ is around 1 then a shift $\sigma = .9$ is reasonable, if we want $A - \sigma I$ to still be positive definite. Starting with the vector of all ones three iteration steps suffice to get the desired accuracy of $\text{tol} = 10^{-5}$, see Table 7.1.

Table 7.1: Computing the lowest eigenvalue of the one-dimensional Poisson equation by inverse iteration

**Example 7.12** We consider the problem of computing the eigenvector corresponding to a known eigenvalue. The matrix that we consider is one of the so-called Wilkinson matrices

$$T = \begin{bmatrix} 19 & -1 & & & \\ -1 & 18 & -1 & & \\ & \ddots & \ddots & \ddots & \\ & -1 & 1 & -1 & \\ & & -1 & 19 & -1 \\ & & & \ddots & \ddots \\ & & & -1 & 20 \end{bmatrix}.$$  

Wilkinson matrices are irreducible tridiagonal matrices that have very close eigenvalues. This matrix has the eigenvalues

</tbody>
</table>

The following MATLAB code constructs the sparse tridiagonal matrix $T$.

```matlab
n = 40;
e = ones(n,1); f = abs([-n/2+1:n/2]');
T = spdiags([-e f -e], [-1:1], n, n);
lam = sort(eig(T));
```
Computing the 20-th and 21-st eigenvectors could be done in the following way.

```matlab
g >> x = (T - lam(20)*eye(n))\e;
>> y = (T - lam(21)*eye(n))\e;
>> x = x/norm(x); y = y/norm(y);
>> x'*y
ans =
  0.00140329005834
>> norm((T - lam(20)*eye(n))*x)
ans =
  7.325760095786749e-15
>> norm((T - lam(21)*eye(n))*y)
ans =
  7.120036319503636e-15
```

The computed vectors \(x\) and \(y\) are good approximations in the sense that they give small residuals. However, the two vectors are not mutually orthogonal at all. We try to improve orthogonality by apply a second step of inverse iteration

```matlab
g >> x = (T - lam(20)*eye(n))\x;
>> y = (T - lam(21)*eye(n))\y;
>> x = x/norm(x); y = y/norm(y);
>> x'*y
ans =
  -1.313592004487587e-05
```

Things have only slightly improved. Therefore, we orthogonalize \(y\) explicitly against \(x\).

```matlab
g >> y = y - x*(x'*y);
>> x'*y
ans =
  -2.155571068436496e-17
>> norm((T - lam(21)*eye(n))*y)
ans =
  1.557058217172078e-15
>> norm((T - lam(20)*eye(n))*x)
ans =
  4.117116818055497e-16
```

This helped. The two eigenvectors are now perpendicular on each other, and the residuals are still fine.

**Discussion of inverse iteration**

We have seen that

- we can compute eigenvectors corresponding to any (simple and well separated) eigenvalue if we choose the shift properly, and that
- we have very good convergence rates, is the shift is close to an eigenvalue.
However, one may feel uncomfortable solving an ‘almost singular’ system of equations, after all \( \sigma \approx \lambda_k \) means that the condition of \( A - \sigma I \) is very big. From the analysis of linear systems of equations we know that this means large errors in the solution. Fortunately, the error that is suffered from when solving with \( A - \sigma I \) points in the right direction. To see this, assume that the singular value decomposition of \( A - \sigma I \) is given by

\[
A - \sigma I = U \Sigma V^*, \quad \Sigma = \text{diag}(\sigma_1, \ldots, \sigma_n), \quad \text{with } \sigma_1 \geq \cdots \geq \sigma_n \geq 0.
\]

If \( A - \sigma I \) is ‘almost’ singular then \( \sigma_n \ll 1 \). If even \( \sigma_n = 0 \) then \( (A - \sigma I)v_n = 0 \), i.e., the last right singular vector is an eigenvector of \( A \) corresponding to the eigenvalue \( \sigma \) (the shift).

If \( \sigma_n = \mathcal{O}(\varepsilon) \) then

\[
(A - \sigma I)z = U \Sigma V^* z = y.
\]

Thus,

\[
z = V \Sigma^{-1} U^* y = \sum_{i=1}^{n} v_i \frac{u_i^* y}{\sigma_i} \approx v_n \frac{u_n^* y}{\sigma_n}.
\]

The tiny \( \sigma_n \) blows up the component in direction of \( v_n \). So, the vector \( z \) points in the desired ‘most singular’ direction.

**7.7 The generalized eigenvalue problem**

Applying the vector iteration (7.1) to the generalized eigenvalue problem \( Ax = \lambda B x \) leads to the iteration

\[
x^{(k)} := B^{-1} Ax^{(k-1)}, \quad k = 1, 2, \ldots
\]

Since the solution of a linear system is required in each iteration step, we can execute an inverse iteration right-away,

\[
(7.27) \quad (A - \sigma B) x^{(k)} := B x^{(k-1)}, \quad k = 1, 2, \ldots
\]

The iteration performs an ordinary vector iteration for the eigenvalue problem

\[
(7.28) \quad (A - \sigma B)^{-1} B x := \mu x, \quad \mu = \frac{1}{\lambda - \sigma}.
\]

Thus, the iteration (7.27) converges to the largest eigenvector of (7.28), i.e., the eigenvector with eigenvalue closest to the shift \( \sigma \).

**7.8 Computing higher eigenvalues**

In order to compute higher eigenvalues \( \lambda_2, \lambda_3, \ldots \), we make use of the mutual orthogonality of the eigenvectors of symmetric matrices, see Theorem 2.14. (In the case of Schur vectors we can proceed in a similar way.)

So, in order to be able to compute the second eigenpair \( (\lambda_2, u_2) \) we have to know the eigenvector \( u_1 \) corresponding to the lowest eigenvalue. Most probably is has been computed previously. If this is the case we can execute an inverse iteration orthogonal to \( u_1 \).

More generally, we can compute the \( j \)-th eigenpair \( (\lambda_j, u_j) \) by inverse iteration, keeping the iterated vector \( x^{(k)} \) orthogonal to the already known or computed eigenvectors \( u_1, \ldots, u_{j-1} \).
Algorithm 7.4 Inverse vector iteration for computing \((\lambda_j, u_j)\)

1. The LU factorization of \(A - \sigma I\): \(LU = P(A - \sigma I)\) and the eigenvectors \(u_1, \ldots, u_{j-1}\) are known.
2. Choose a starting vector \(x^{(0)}\) such that \(u_j^*x^{(0)} = 0, q < j\).
3. Set \(k := 0\).
4. while \(\|x^{(k)} - y^{(k)}/\mu^{(k)}\| > \text{tol}\|y^{(k)}\|\) do
5. \(k := k + 1;\)
6. \(x^{(k)} := y^{(k-1)}/\|y^{(k-1)}\|;\)
7. \(y^{(k)} := U^{-1}L^{-1}P x^{(k)};\)
8. \(\mu^{(k)} := y^{(k)^*x^{(k)}}, \lambda^{(k)} := \sigma + 1/\mu^{(k)}.\)
9. end while

In exact arithmetic, the condition \(u_j^*x^{(0)} = \cdots = u_{j-1}^*x^{(0)} = 0\) implies that all \(x^{(k)}\) are orthogonal to \(u_1, \ldots, u_{j-1}\). In general, however, one has to expect rounding errors that introduce components in the directions of already computed eigenvectors. Therefore, it is necessary to enforce the orthogonality conditions during the iteration.

Assuming exact arithmetic, Theorem 7.10 immediately implies that

\[
\sin \angle (x^{(k)}, x_j) \leq c_1 \left( \frac{\lambda_j}{\lambda_{j'}} \right)^k
\]

\[
|\lambda^{(k)} - \lambda_j| \leq c_2 \left( \frac{\lambda_j}{\lambda_{j'}} \right)^2
\]

where \(j'\) is the smallest index for which \(\lambda_{j'} > \lambda_j\).

7.9 Rayleigh quotient iteration

We now assume that the matrix the eigenpairs of which we want to determine is Hermitian (or symmetric).

We have noticed that inverse iteration is an effective way to compute eigenpairs, if a good approximation of the desired eigenvalue is known. This approximation is used as a shift. However, as we have seen earlier, if a good approximation of an eigenvector is available its Rayleigh quotient gives a very good approximation of its eigenvalue.

Indeed we have the following

Lemma 7.13 Let \(q\) be any nonzero vector. The number \(\rho\) that minimizes \(\|Aq - \rho q\|\) is the Rayleigh quotient

\[
(7.29) \quad \rho = \frac{q^*Aq}{q^*q}.
\]

Proof. Let \(\rho \in \mathbb{R}\) be the Rayleigh quotient (7.29) of \(q \neq 0\) and let \(\tau \in \mathbb{C}\) be any number. Then we have

\[
\|Aq - (\rho + \tau)q\|^2 = q^*A^2q - (2\rho + \tau + \tau^*)q^*Aq + |\rho + \tau|^2q^*q
\]

\[
= q^*A^2q - 2\rho q^*Aq - 2\text{Re}(\tau)q^*Aq + \rho^2q^*q + 2\rho\text{Re}(\tau)q^*q + |\tau|^2q^*q
\]

\[
= q^*A^2q - \frac{(q^*Aq)^2}{q^*q} + |\tau|^2q^*q.
\]

The last term is smallest if \(\tau = 0\).
Algorithm 7.5 Rayleigh quotient iteration (RQI)
1: Choose a starting vector $y_0 \in \mathbb{F}^n$ with $\|y_0\| = 1$ and a tolerance $\varepsilon$.
2: for $k = 1, 2, \ldots$ do
3: \[ \rho^{(k)} := y^{(k-1)*}Ay^{(k-1)}. \]
4: Solve $(A - \rho^{(k)} I)z^{(k)} = y^{(k-1)}$ for $z^{(k)}$.
5: \[ \sigma^{(k)} = \|z^{(k)}\|. \]
6: \[ y^{(k)} := z^{(k)}/\sigma^{(k)}. \]
7: if $\sigma^{(k)} > 10/\varepsilon$ then
8: \[ \text{return } \{y^{(k)}\} \]
9: end if
10: end for

The following algorithm 7.9 is a modification of inverse iteration. In each iteration step the shift is modified to be the Rayleigh quotient of the most recent eigenvector approximation. This is not a curse but a blessing [4] as we have seen in section 7.6.

In step 4 of this algorithm a close to singular system of equation is solved. This results in a very long solution whose norm is used as the convergence criterion.

The Rayleigh quotient iteration usually converges, however not always towards the desired solution. Therefore, to investigate the convergence rate we make the following assumption:

Assumption: \[ y^{(k)} \xrightarrow[k \to \infty]{} x \text{ with } Ax = \lambda x. \]

This assumption guarantees that there is at all convergence towards a certain eigenvector $x$. Let $\|x\| = \|y^{(k)}\| = 1$ and let the angle between this eigenvector and its approximation be $\phi^{(k)} = \angle(x, y^{(k)})$. Then the assumption implies that $\{\phi^{(k)}\}_{k=1}^\infty$ converges to zero. We can write

\[ y^{(k)} = x \cos \phi^{(k)} + u^{(k)} \sin \phi^{(k)}, \quad \|x\| = \|y^{(k)}\| = \|u^{(k)}\| = 1. \]

Let

\[ \rho^{(k)} = \rho(y^{(k)}) = \frac{y^{(k)*}Ay^{(k)}}{y^{(k)*}y^{(k)}} = y^{(k)*}Ay^{(k)} \]

be the Rayleigh quotient of $y_k$. Then we have

\[ \lambda - \rho_k = \lambda - \cos^2 \phi_k \frac{x^*Ax}{\lambda} - \cos \phi_k \sin \phi_k \frac{x^*Au_k}{0} - \sin^2 \phi_k u_k^*Au_k \]

\[ = \lambda(1 - \cos^2 \phi_k) - \sin^2 \phi_k \rho(u_k) \]

\[ = (\lambda - \rho(u_k)) \sin^2 \phi_k. \]

We now prove the

Theorem 7.14 (Local convergence of Rayleigh quotient iteration) With the above assumption we have

\[ \lim_{k \to \infty} \frac{\phi_{k+1}}{\phi_k^3} \leq 1. \]

i.e., RQI converges cubically.

Proof. (The proof follows closely the one given by Parlett [4].) We have

\[ z_{k+1} = (A - \rho_k I)^{-1}y_k = x \cos \phi_k/(\lambda - \rho_k) + (A - \rho_k I)^{-1}u_k \sin \phi_k \]

\[ = x \cos \phi_k/(\lambda - \rho_k) + u_{k+1} \sin \phi_k \|A(\lambda - \rho_k I)^{-1}u_k\|, \]

\[ \|z_{k+1}\| \cos \phi_{k+1} \quad \|z_{k+1}\| \sin \phi_{k+1} \]
where we set

\[ u_{k+1} := (A - \rho_k I)^{-1}u_k/\|(A - \rho_k I)^{-1}u_k\| \]

such that \( \|u_{k+1}\| = 1 \) and \( u^*_k \perp x = 0 \). Thus,

\[
\tan \varphi_{k+1} = \sin \varphi_{k+1}/\cos \varphi_{k+1}
= \sin \varphi_k \|(A - \rho_k I)^{-1}u_k\| (\lambda - \rho_k)/\cos \varphi_k
= (\lambda - \rho_k)\|(A - \rho_k I)^{-1}u_k\| \tan \varphi_k
= (\lambda - \rho(u_k))\|(A - \rho_k I)^{-1}u_k\| \sin^2 \varphi_k \tan \varphi_k.
\]

So,

\[
(A - \rho_k I)^{-1}u_k = (A - \rho_k I)^{-1} \left( \sum_{\lambda_i \neq \lambda} \beta_i x_i \right) = \sum_{\lambda_i \neq \lambda} \frac{\beta_i}{\lambda_i - \rho_k} x_i
\]

and taking norms,

\[
\|(A - \rho_k I)^{-1}u_k\|^2 = \sum_{\lambda_i \neq \lambda} \frac{\beta_i^2}{|\lambda_i - \rho_k|^2} \geq \frac{1}{\min_{\lambda_i \neq \lambda} |\lambda_i - \rho_k|^2} \sum_{\lambda_i \neq \lambda} \beta_i^2
\]

We define the gap between the eigenvalue \( \lambda \) and the rest of \( A \)'s spectrum by

\[
\gamma := \min_{\lambda_i \neq \lambda} |\lambda_i - \lambda|.
\]

The assumption implies that there must be a \( k_0 \in \mathbb{N} \) such that \( |\lambda - \rho_k| < \frac{\gamma}{2} \) for all \( k > k_0 \), and, therefore,

\[
|\lambda_i - \rho_k| > \frac{\gamma}{2} \quad \text{for all } \lambda_i \neq \lambda.
\]

Using this in (7.32) gives

\[
\|(A - \rho_k I)^{-1}u_k\| \leq \frac{1}{\min_{\lambda_i \neq \lambda} |\lambda_i - \rho_k|} \leq \frac{2}{\gamma}, \quad k > k_0.
\]

Because \( \tan \varphi_k \approx \sin \varphi_k \approx \varphi_k \) if \( \varphi_k \ll 1 \) we can deduce the cubic convergence rate.

We now look at the sequence \( \{u_k\} \) more closely. We note from (7.31) that this sequence is obtained by “inverse iteration with variable shift \( \rho_k \).” But since \( \rho_k \longrightarrow \lambda \) with a cubic rate of convergence we can for large \( k \) assume that \( \rho_k = \lambda \) and that \( u_k \perp x \).

We now consider two cases, either \( \{u_k\} \) converges, or it does not converge.

1. We assume that \( \{u_k\} \) converges. Then the limit vector \( \hat{u} \) must be an eigenvector of \( A \) in \( \text{span}\{x\}^\perp \). (In general, \( \hat{u} \) is an eigenvector corresponding to the eigenvalue \( \hat{\lambda} \) that is closest to \( \lambda \).) Thus,

\[
(\lambda - \rho(u_k))\|(A - \rho_k I)^{-1}u_k\| \longrightarrow_{k \rightarrow \infty} \pm|\lambda - \hat{\lambda}| \cdot \|\hat{u}/(\lambda - \hat{\lambda})\| = \pm 1.
\]

2. Now we assume that \( \{u_k\} \) does not converge. Then \( A \) has two eigenvalues of equal distance to \( \lambda \) and the cluster points of the sequence \( \{u_k\} \) are two vectors in the plane.
that is spanned by two eigenvectors corresponding to these two eigenvalues \( \lambda \pm \delta \), \( \alpha \mathbf{x}_p + \beta \mathbf{x}_q \), where \( \alpha \neq 0 \), \( \beta \neq 0 \), and \( \alpha^2 + \beta^2 = 1 \). Their Rayleigh quotients are

\[
\rho(\alpha \mathbf{x}_p + \beta \mathbf{x}_q) = \alpha^2 \lambda_p + \beta^2 \lambda_q = \alpha^2(\lambda \pm \delta) + \beta^2(\lambda \mp \delta) = \lambda \pm \delta(\alpha^2 - \beta^2).
\]

As \( k \to \infty \) the Rayleigh quotients of \( \mathbf{u}_k \) jump between these two values. Hence,

\[
(\lambda - \rho(\mathbf{u}_k))\|(A - \rho_k I)^{-1}\mathbf{u}_k\| \to \pm \delta(\alpha^2 - \beta^2)/\delta,
\]

and, therefore,

\[
\left| \frac{\varphi_{k+1}}{\varphi_k} \right| \xrightarrow{k \to \infty} |\alpha^2 - \beta^2| < 1.
\]

**Remark 7.6.** Notice that we have not proved global convergence. Regarding this issue consult the book by Parlett [4] that contains all of this and more.

RQI converges ‘almost always’. However, it is not clear in general towards which eigenpair the iteration converges. So, it is wise to start RQI only with good starting vectors. An alternative is to first apply inverse vector iteration and switch to Rayleigh quotient iteration as soon as the iterate is close enough to the solution. For references on this technique see [6, 1].

**Remark 7.7.** The Rayleigh quotient iteration is expensive. In every iteration step another system of equations has to be solved, i.e., in every iteration step a matrix has to be factorized. Therefore, RQI is usually applied only to tridiagonal matrices.

### 7.9.1 A numerical example

The following MATLAB script demonstrates the power of Rayleigh quotient iteration. It expects as input a matrix \( A \), an initial vector \( \mathbf{x} \) of length one.

```matlab
% Initializations
k = 0; rho = 0; ynorm = 0;

while abs(rho)*ynorm < 1e+15,
    k = k + 1; if k>20, break, end
    rho = x'*A*x;
    y = (A - rho*eye(size(A)))\x;
    ynorm = norm(y);
    x = y/ynorm;
end

We invoked this routine with the matrix

\[
A = \begin{bmatrix}
2 & -1 & & & & & & \\
-1 & 2 & -1 & & & & & \\
& & \ddots & \ddots & \ddots & & & \\
& & & -1 & 2 & -1 & & \\
& & & & -1 & 2 & & \\
& & & & & & \ddots & \\
\end{bmatrix} \in \mathbb{R}^{9 \times 9}
\]

and the initial vector \( \mathbf{x} = [-4, -3, \ldots, 4]^T \). The numbers obtained are

The cubic convergence is evident.

Bibliography

Chapter 8

Simultaneous vector or subspace iterations

8.1 Basic subspace iteration

We have learned in subsection 7.8 how to compute several eigenpairs of a matrix, one after the other. This turns out to be quite inefficient. Some or several of the quotients $\lambda_{i+1}/\lambda_i$ may be close to one. The following algorithm differs from Algorithm 7.8 in that it does not perform $p$ individual iterations for computing the, say, $p$ smallest eigenvalues, but a single iteration with $p$ vectors simultaneously.

Algorithm 8.1 Basic subspace iteration

1: Let $X \in \mathbb{F}^{n \times p}$ be a matrix with orthnormalized columns, $X^*X = I_p$. This algorithm computes eigenvectors corresponding to the $p$ largest eigenvalues $\lambda_1 \geq \cdots \geq \lambda_p$ of $A$.
2: Set $X^{(0)} := X$, $k = 1$
3: while $\| (I - X^{(k)}X^{(k)^*}X^{(k-1)}) \| > tol$ do
4: $k := k + 1$
5: $Z^{(k)} := AX^{(k-1)}$
6: $X^{(k)}R^{(k)} := Z^{(k)}/\ast$ QR factorization of $Z^{(k)}$ /n
7: end while

The QR factorization in step 6 of the algorithm prevents the columns of the $X^{(k)}$ from converging all to an eigenvector of largest modulus.

If the convergence criterion is satisfied then

$$X^{(k)} - X^{(k-1)}(X^{(k-1)^*}X^{(k)}) = E, \quad \text{with} \quad \|E\| \leq tol.$$

Therefore, for the ‘residual’,

$$AX^{(k-1)} - X^{(k-1)}(X^{(k-1)^*}X^{(k)})R^{(k)} = ER^{(k)},$$

Therefore, in case of convergence, $X^{(k)}$ tends to an invariant subspace, say $\mathcal{R}(X_\ast)$. $X^{(k-1)^*}X^{(k)} \approx I_p$ and $AX^{(k)} = X^{(k)}R^{(k)}$ is an approximation of a partial Schur decomposition. We will show that the matrix $X^{(k)}$ converges to the Schur vectors associated with the largest $p$ eigenvalues of $A$. In the convergence analysis we start from the Schur decomposition $A = UTU^*$ of $A$.

It is important to notice that in the QR factorization of $Z^{(k)}$ the $j$-th column affects only the columns to its right. If we would apply Algorithm 8.1 to a matrix $\hat{X} \in \mathbb{F}^{n \times q}$, with
CHAPTER 8. SIMULTANEOUS VECTOR OR SUBSPACE ITERATIONS

$Xe_i = \hat{X}e_i$ for $i = 1, \ldots, q$ then, for all $k$, we would have $X^{(k)}e_i = \hat{X}^{(k)}e_i$ for $i = 1, \ldots, j$. This, in particular, means that the first columns $X^{(k)}e_1$ perform a simple vector iteration.

Problem 8.1 Show by recursion that the QR factorization of $A^kX = A^kX^{(0)}$ is given by

$$A^kX = X^{(k)}R^{(k)}R^{(k-1)}\cdots R^{(1)}.$$  

8.2 Angles between subspaces

In the convergence analysis of the subspace iteration we need the notion of an angle between subspaces. Let $Q_1 \in \mathbb{F}^{n \times p}$, $Q_2 \in \mathbb{F}^{n \times q}$ be matrices with orthonormal columns, $Q_1^*Q_1 = I_p$, $Q_2^*Q_2 = I_q$. Let $S_i = \mathcal{R}(Q_i)$. Then $S_1$ and $S_2$ are subspaces of $\mathbb{F}^n$ of dimension $p$ and $q$, respectively. We want to investigate how we can define a distance or an angle between $S_1$ and $S_2$.

It is certainly straightforward to define the angle between the subspaces $S_1$ and $S_2$ to be the angle between two vectors $x_1 \in S_1$ and $x_2 \in S_2$. It is, however, not clear right-away how these vectors should be chosen. Let us consider the case of two 2-dimensional subspaces in $\mathbb{R}^3$, cf. Fig. (8.1). Let $S_1 = \text{span}\{q_1, q_2\}$ and $S_2 = \text{span}\{q_1, q_3\}$ where we assume that $q_1^*q_2 = q_1^*q_3 = 0$. We might be tempted to define the angle between $S_1$ and $S_2$ as the maximal angle between any two vectors in $S_1$ and $S_2$.

$$\angle(S_1, S_2) = \max_{\substack{x_1 \in S_1 \\ x_2 \in S_2}} \angle(x_1, x_2). \tag{8.1}$$

This would give an angle of $90^\circ$ as we could chose $q_1$ in $S_1$ and $q_3$ in $S_2$. This angle would not change as we turn $S_2$ around $q_1$. It would even stay the same if the two planes coincided.

What if we would take the minimum in (8.1)? This definition would be equally unsatisfactory as we could chose $q_1$ in $S_1$ as well as in $S_2$ to obtain an angle of $0^\circ$. In fact, any two 2-dimensional subspaces in 3 dimensions would have an angle of $0^\circ$. Of course, we would like to reserve the angle of $0^\circ$ to coinciding subspaces.

A way out of this dilemma is to proceed as follows: Take any vector $x_1 \in S_1$ and determine the angle between $x_1$ and its orthogonal projection $(I - Q_2^*Q_2)x_1$ on $S_2$. We now maximize the angle by varying $x_1$ among all non-zero vectors in $S_1$. In the above 3-dimensional example we would obtain the angle between $x_2$ and $x_3$ as the angle between
8.2. ANGLES BETWEEN SUBSPACES

S1 and S3. Is this a reasonable definition? In particular, is it well-defined in the sense that it does not depend on how we number the two subspaces? Let us now assume that S1, S2 ⊂ F^n have dimensions p and q. Formally, the above procedure gives an angle θ with

\begin{equation}
\sin \theta := \max_{r \in S_1} \| (I_n - Q_2 Q_2^*) r \| = \max_{a \in F^p} \| (I_n - Q_2 Q_2^*) Q_1 a \|
\end{equation}

(8.2)

Because \( I_n - Q_2 Q_2^* \) is an orthogonal projection, we get

\begin{equation}
\| (I_n - Q_2 Q_2^*) Q_1 a \|^2 = a^* Q_1^* (I_n - Q_2 Q_2^*) (I_n - Q_2 Q_2^*) Q_1 a
= a^* Q_1^* (I_n - Q_2 Q_2^*) Q_1 a
= a^* (Q_1 Q_1^* - Q_2 Q_2^* Q_1) a
= a^* (I_p - (Q_1 Q_2)(Q_2 Q_1)) a
= a^* (I_p - W W^*) a
\end{equation}

(8.3)

where W := Q_2 Q_1 ∈ F_q x p. With (8.2) we obtain

\begin{equation}
\sin^2 \theta = \max_{\|a\|=1} a^* (I_p - W W^*) a
\end{equation}

(8.4)

= largest eigenvalue of I_p - W W^* = 1 - smallest eigenvalue of W W^*.

If we change the roles of Q_1 and Q_2 we get in a similar way

\begin{equation}
\sin^2 \varphi = \| (I_n - Q_1 Q_1^*) Q_2 \| \; 1 - \text{smallest eigenvalue of WW}^*.
\end{equation}

(8.5)

Notice, that W W^* ∈ F_p x p and WW^* ∈ F_q x q and that both matrices have equal rank. Thus, if W has full rank and \( p < q \) then \( \theta < \varphi = \pi/2 \). However if \( p = q \) then W W^* and WW^* have equal eigenvalues, and, thus, \( \theta = \varphi \). In this most interesting case we have

\begin{equation}
\sin^2 \theta = 1 - \lambda_{\text{min}}(W W^*) = 1 - \sigma_{\text{min}}^2(W),
\end{equation}

where \( \sigma_{\text{min}}(W) \) is the smallest singular value of W [2, p.16].

For our purposes in the analysis of eigenvalue solvers the following definition is most appropriate.

**Definition 8.2** Let S_1, S_2 ⊂ F^n be of dimensions p and q and let Q_1 ∈ F^{n x p} and Q_2 ∈ F^{n x q} be matrices the columns of which form orthonormal bases of S_1 and S_2, respectively, i.e. \( S_i = R(Q_i), i = 1, 2 \). Then we define the angle θ, \( 0 \leq \theta \leq \pi/2 \), between S_1 and S_2 by

\begin{equation}
\sin \theta = \sin \angle (S_1, S_2) = \begin{cases} 
\sqrt{1 - \sigma_{\text{min}}^2(Q_1 Q_2)} & \text{if } p = q, \\
1 & \text{if } p \neq q.
\end{cases}
\end{equation}

If p = q the equations (8.2)–(8.4) imply that

\begin{equation}
\sin^2 \theta = \max_{\|a\|=1} a^* (I_p - W W^*) a = \max_{\|b\|=1} b^* (I_p - W W^*) b
\end{equation}

(8.6)

\begin{align*}
&= \| (I_n - Q_2 Q_2^*) Q_1 \| = \| (I_n - Q_1 Q_1^*) Q_2 \|
&= \| (Q_1 Q_1^* - Q_2 Q_2^*) Q_1 \| = \| (Q_1 Q_1^* - Q_2 Q_2^*) Q_2 \|
\end{align*}
Let \( x \in S_1 + S_2 \). Then \( x = \tilde{q}_1 + \tilde{q}_2 \) with \( \tilde{q}_i \in S_i \). We write
\[
x = q_1 + Q_1^* q_2 + (I_n - Q_1^*) \tilde{q}_2 =: q_1 + q_2
\]
with \( q_1 = Q_1 a \) and \( q_2 = Q_2 b = (I_n - Q_1^*) Q_2 b \). Then
\[
\|(Q_1 Q_1^* - Q_2 Q_2^*) x \|^2 = \|(Q_1 Q_1^* - Q_2 Q_2^*)(Q_1 a + Q_2 b)\|^2 \\
= \|Q_1 a + Q_2 Q_2^* a + Q_2 b\|^2 \\
= \|(I_n - Q_2 Q_2^*) a + Q_2 b\|^2 \\
= a^* Q_1^* (I_n - Q_2 Q_2^*) Q_1 a \\
+ 2 \text{Re}(a^* Q_1^* (I_n - Q_2 Q_2^*) Q_2 b) + b^* Q_2^* Q_2 b
\]
\[
\sin^2 \vartheta = \max_{\|a\|=1} a^* Q_1^* (I_n - Q_2 Q_2^*) Q_1 a, \\
= \max_{\|a\|=1} a^* Q_1^* (Q_1 Q_1^* - Q_2 Q_2^*) Q_1 a, \\
= \max_{x \in S_1 \setminus \{0\}} \frac{x^* (Q_1 Q_1^* - Q_2 Q_2^*) x}{x^* x}.
\]
Thus, \( \sin \vartheta \) is the maximum of the Rayleigh quotient \( R(x) \) corresponding to \( Q_1 Q_1^* - Q_2 Q_2^* \), that is the largest eigenvalue of \( Q_1 Q_1^* - Q_2 Q_2^* \). As \( Q_1 Q_1^* - Q_2 Q_2^* \) is symmetric and positive semi-definite, its largest eigenvalue equals its norm,

**Lemma 8.3** \[ \sin \angle(S_1, S_2) = \|Q_2 Q_2^* - Q_1 Q_1^*\| \]

**Lemma 8.4** \[ \angle(S_1, S_2) = \angle(S_1^\perp, S_2^\perp). \]

**Proof.** Because
\[
\|Q_2 Q_2^* - Q_1 Q_1^*\| = \|(I - Q_2 Q_2^*) - (I - Q_1 Q_1^*)\|
\]
the claim immediately follows from Lemma 8.3.

### 8.3 Convergence of basic subspace iteration

In analyzing the convergence of the basic subspace iteration we proceed similarly as in the analysis of the simple vector iteration, exploiting the Jordan normal form \( A = X J Y^* \) with \( Y^*: = X^{-1} \). We assume that the \( p \) largest eigenvalues of \( A \) in modulus are separated from the rest of the spectrum,

\[
(8.7) \quad |\lambda_1| \geq \cdots \geq |\lambda_p| > |\lambda_{p+1}| \geq \cdots \geq |\lambda_n|.
\]

This means that the eigenvalues are arranged on the diagonal of the Jordan block matrix \( J \) in the order given in (8.7).

In fact as we can either analyze the original iteration \( \{X^{(k)}\} \) in the canonical coordinate system or the iteration \( \{Y^{(k)} \} = \{U^* X^{(k)} \} \) in the coordinate system generated by the (generalized) eigenvectors we assume that \( A \) itself is a Jordan block matrix with its diagonal elements arranged as in (8.7).

The invariant subspace of \( A \) associated with the \( p \) largest (or dominant) eigenvalues is given by \( \mathcal{R}(E_p) \) where \( E_p = [e_1, \ldots, e_p] \). We are now going to show that the angle between \( \mathcal{R}(X^{(k)}) \) and \( \mathcal{R}(E_p) \), tends to zero as \( k \) goes to \( \infty \).

From Problem 8.1 we know that
\[
\vartheta^{(k)} := \angle(\mathcal{R}(E_p), \mathcal{R}(X^{(k)})) = \angle(\mathcal{R}(E_p), \mathcal{R}(A^k X^{(0)})).
\]
8.3. CONVERGENCE OF BASIC SUBSPACE ITERATION

We partition the matrices $A$ and $X^{(k)}$,

$$A = \text{diag}(J_1, J_2), \quad X^{(k)} = \begin{bmatrix} X_1^{(k)} \\ X_2^{(k)} \end{bmatrix}, \quad J_1, X_1^{(k)} \in \mathbb{F}^{p \times p}.$$

From (8.7) we know that $J_1$ is nonsingular. Let us also assume that $X_1^{(k)} = E_p^* X^{(k)}$ is invertible. This means, that $X^{(k)}$ has components in the direction of the invariant subspace associated with the $p$ dominant eigenvalues. Then, with Problem 8.1,

$$X^{(k)} R = A^k X^{(0)} = \begin{bmatrix} J_1^k X_1^{(0)} \\ J_2^k X_2^{(0)} \end{bmatrix} = \begin{bmatrix} I_p & J_1^k \\ S^{(k)} & I_p \end{bmatrix} J_1^k X_1^{(0)}, \quad S^{(k)} := J_2^k X_2^{(0)} X_1^{(0)^{-1}} J_1^{-k}.$$

Notice that $X_1^{(k)}$ is invertible if $X_1^{(0)}$ is so. (8.8) and (8.9) imply that

$$\sin \vartheta^{(k)} = \| (I - E_p E_p^*) X^{(k)} \| = \left\| \begin{bmatrix} I_p \\ S^{(k)} \end{bmatrix} \right\| / \left\| \begin{bmatrix} I_p \\ S^{(k)} \end{bmatrix} \right\| = \frac{\| S^{(k)} \|}{\sqrt{1 + \| S^{(k)} \|^2}}.$$

Likewise, we have

$$\cos \vartheta^{(k)} = \| E_p^* X^{(k)} \| = \frac{1}{\sqrt{1 + \| S^{(k)} \|^2}}.$$

Since $\rho(J_2) = |\lambda_{p+1}|$ and $\rho(J_1^{-1}) = 1/|\lambda_p|$ we obtain with (7.13) and a few algebraic manipulations for any $\varepsilon > 0$ that

$$\tan \vartheta^{(k)} = \| S^{(k)} \| \leq \| J_2^k \| \| S^{(0)} \| \| J_1^{-k} \| \leq \left( \frac{\lambda_{p+1}}{\lambda_p} + \varepsilon \right)^k \tan \vartheta^{(0)},$$

for $k > K(\varepsilon)$. Making a transformation back to a general matrix $A$ as before Theorem 7.5 we get

**Theorem 8.5** Let $U_p, V_p \in \mathbb{F}^{n \times p}, U_p^* U_p = V_p^* V_p = I_p,$ be matrices that span the right and left invariant subspace associated with the dominant $p$ eigenvalues $\lambda_1, \ldots, \lambda_p$ of $A$. Let $X^{(0)} \in \mathbb{F}^{n \times p}$ be such that $V_p^* X^{(0)}$ is nonsingular. Then, if $|\lambda_p| < |\lambda_{p+1}|$ and $\varepsilon > 0$, the iterates $X^{(k)}$ of the basic subspace iteration with initial subspace $X^{(0)}$ converges to $U_p$, and

$$\tan \vartheta^{(k)} \leq \left( \frac{\lambda_{p+1}}{\lambda_p} + \varepsilon \right)^k \tan \vartheta^{(0)}, \quad \vartheta^{(k)} = \angle(\mathcal{R}(U_p), \mathcal{R}(X^{(k)}))$$

for sufficiently large $k$.

If the matrix $A$ is Hermitian or real-symmetric we can simplify Theorem 8.5.

**Theorem 8.6** Let $U_p := [u_1, \ldots, u_p]$ be the matrix formed by the eigenvectors corresponding to the $p$ dominant eigenvalues $\lambda_1, \ldots, \lambda_p$ of $A$. Let $X^{(0)} \in \mathbb{F}^{n \times p}$ be such that $U_p^* X^{(0)}$ is nonsingular. Then, if $|\lambda_p| < |\lambda_{p+1}|$, the iterates $X^{(k)}$ of the basic subspace iteration with initial subspace $X^{(0)}$ converges to $U_p$, and

$$\tan \vartheta^{(k)} \leq \left( \frac{\lambda_{p+1}}{\lambda_p} \right)^k \tan \vartheta^{(0)}, \quad \vartheta^{(k)} = \angle(\mathcal{R}(U_p), \mathcal{R}(X^{(k)}))$$

for sufficiently large $k$. 
Let us elaborate on this result. (Here we assume that $A$ is Hermitian or real-symmetric. Otherwise the statements are similar modulo $\varepsilon$ terms as in (8.12).) Let us assume that not only $W_p := U_p^*X$ is nonsingular but that each principal submatrix

$$W_j := \begin{pmatrix} w_{11} & \cdots & w_{1j} \\ \vdots & & \vdots \\ w_{j1} & \cdots & w_{jj} \end{pmatrix}, \quad 1 \leq j \leq p,$$

of $W_p$ is nonsingular. Then we can apply Theorem 8.6 to each set of columns $[x_1^{(k)}, \ldots, x_j^{(k)}]$, $1 \leq j \leq p$, provided that $|\lambda_j| < |\lambda_{j+1}|$. If this is the case, then

$$\tan \vartheta_j^{(k)} \leq \left| \frac{\lambda_{j+1}}{\lambda_j} \right|^k \tan \vartheta_j^{(0)},$$

where $\vartheta_j^{(k)} = \angle(\mathcal{R}([u_1, \ldots, u_j]), \mathcal{R}([x_1^{(k)}, \ldots, x_j^{(k)}]))$.

We can even say a little more. We can combine the statements in (8.14) as follows.

**Theorem 8.7** Let $X \in \mathbb{F}^{n \times p}$. Let $|\lambda_{q-1}| > |\lambda_q| \geq \ldots \geq |\lambda_p| > |\lambda_{p+1}|$. Let $W_q$ and $W_p$ be nonsingular. Then

$$\sin \angle(\mathcal{R}([x_q^{(k)}], \ldots, x_p^{(k)}]), \mathcal{R}([u_q, \ldots, u_p])) \leq c \cdot \max \left\{ \left| \frac{\lambda_q}{\lambda_{q-1}} \right|^k, \left| \frac{\lambda_{p+1}}{\lambda_p} \right|^k \right\}.$$

**Proof.** Recall that the sine of the angle between two subspaces $S_1, S_2$ of equal dimension is the norm of the projection on $S_2^\perp$ restricted to $S_1$, see (8.6). Here, $S_1 = \mathcal{R}([x_q^{(k)}, \ldots, x_p^{(k)}])$ and $S_2 = \mathcal{R}([u_q, \ldots, u_p])$.

Let $x \in S_1$ with $\|x\| = 1$. The orthogonal projection of $x$ on $S_2$ reflects the fact, that $y \in \mathcal{R}([u_q, \ldots, u_p])$ implies that $y \in \mathcal{R}([u_1, \ldots, u_p])$ as well as $y \in \mathcal{R}([u_1, \ldots, u_q]^\perp$, $U_{q-1}U_{q-1}^*x + (I - U_pU_p^*)x$.

To estimate the norm of this vector we make use of Lemmata 8.4 and (8.10),

$$\|U_{q-1}U_{q-1}^*x + (I - U_pU_p^*)x\| = (\|U_{q-1}U_{q-1}^*x\|^2 + \|(I - U_pU_p^*)x\|^2)^{1/2} \leq \left( \sin^2 \vartheta_{q-1}^{(k)} + \sin^2 \vartheta_p^{(k)} \right)^{1/2} \leq \sqrt{2} \cdot \max \left\{ \sin \vartheta_{q-1}^{(k)}, \sin \vartheta_p^{(k)} \right\} \cdot \tan \vartheta_{q-1}^{(k)}, \tan \vartheta_p^{(k)} \right\}.$$

Then, inequality (8.15) is obtained by applying (8.14) that we know to hold true for both $j = q - 1$ and $j = p$. \hfill \[\Box\]

**Corollary 8.8** Let $X \in \mathbb{F}^{n \times p}$. Let $|\lambda_{j-1}| > |\lambda_j| > |\lambda_{j+1}|$ and let $W_{j-1}$ and $W_j$ be nonsingular. Then

$$\sin \angle(x_j^{(k)}, u_j) \leq c \cdot \max \left\{ \left| \frac{\lambda_j}{\lambda_{j-1}} \right|^k, \left| \frac{\lambda_{j+1}}{\lambda_j} \right|^k \right\}.$$

**Example 8.9** Let us see how subspace iteration performs with the matrix $A = \text{diag}(1, 3, 4, 6, 10, 15, 20, \ldots, 185)^{-1} \in \mathbb{R}^{40 \times 40}$

if we iterate with 5 vectors. The critical quotients appearing in Corollary 8.8 are
So, according to (8.16), the first column \( x_1^{(k)} \) of \( X^{(k)} \in \mathbb{R}^{40 \times 5} \) should converge to the first eigenvector at a rate 1/3, \( x_2^{(k)} \) and \( x_3^{(k)} \) should converge at a rate 3/4 and the last two columns should converge at the rate 2/3. The graphs in Figure 8.2 show that convergence takes place in exactly this manner.

Similarly as earlier the eigenvalue approximations \( \lambda_j^{(k)} \) approach the desired eigenvalues more rapidly than the eigenvectors. In fact we have

\[
\lambda_j^{(k+1)^2} = \| z_j^{(k+1)} \|^2 = \frac{x_j^{(k)^*} A^2 x_j^{(k)}}{x_j^{(k)^*} x_j^{(k)}} = x_j^{(k)^*} A^2 x_j^{(k)},
\]

since \( \| x_j^{(k)} \| = 1 \). Let \( x_j^{(k)} = u + u^\perp \), where \( u \) is the eigenvalue corresponding to \( \lambda_j \). Then, since \( u = x_j^{(k)} \cos \phi \) and \( u^\perp = x_j^{(k)} \sin \phi \) for a \( \phi \leq \vartheta^{(k)} \), we have

\[
\lambda_j^{(k+1)^2} = x_j^{(k)^*} A^2 x_j^{(k)} = u^* A u + u^\perp^* A u^\perp = \lambda_j^2 u^* u + u^\perp^* A u^\perp \\
\leq \lambda_j^2 \| u \|^2 + \lambda_j^2 \| u^\perp \|^2 \\
\leq \lambda_j^2 \cos^2 \vartheta^{(k)} + \lambda_j^2 \sin^2 \vartheta^{(k)} \\
= \lambda_j^2 (1 - \sin^2 \vartheta^{(k)}) + \lambda_j^2 \sin^2 \vartheta^{(k)} = \lambda_j^2 + (\lambda_j^2 - \lambda_j^2) \sin^2 \vartheta^{(k)}.
\]

Thus,

\[
|\lambda_j^{(k+1)} - \lambda_j| \leq \frac{\lambda_j^2 - \lambda_j^{(k+1)^2}}{\lambda_j^{(k+1)} + \lambda_j^2} \sin^2 \vartheta^{(k)} = O \left( \max \left\{ \left( \frac{\lambda_j}{\lambda_j} \right)^k, \left( \frac{\lambda_j+1}{\lambda_j} \right)^k \right\} \right).
\]
Table 8.1: Example of basic subspace iteration.

The convergence criterion $\| (I - X^{(k-1)} X^{(k-1)^*}) x^{(k)} \| < 10^{-6}$ was satisfied after 87 iteration steps.
A numerical example

Let us again consider the test example introduced in subsection 1.6.3 that deals with the acoustic vibration in the interior of a car. The eigenvalue problem for the Laplacian is solved by the finite element method as introduced in subsection 1.6.2. We use the finest grid in Fig. 1.9. The matrix eigenvalue problem

\[ Ax = \lambda Bx, \quad A, B \in \mathbb{F}^{n \times n}, \]

has the order \( n = 1095 \). Subspace iteration is applied with five vectors as an inverse iteration to

\[ L^{-1}AL^{-T}(Lx) = \lambda(Lx), \quad B = LL^T. \quad \text{(Cholesky factorization)} \]

\( X^{(0)} \) is chosen to be a random matrix. Here, we number the eigenvalues from small to big.

The smallest six eigenvalues of (8.17) shifted by 0.01 to the right are

\[ \hat{\lambda}_1 = 0.01, \quad \hat{\lambda}_4 = 0.066635, \]
\[ \hat{\lambda}_2 = 0.022690, \quad \hat{\lambda}_5 = 0.126631, \]
\[ \hat{\lambda}_3 = 0.054385, \quad \hat{\lambda}_6 = 0.147592. \]

and thus the ratios of the eigenvalues that determine the rate of convergence are

\[ \frac{\hat{\lambda}_1}{\hat{\lambda}_2}\gamma^2 = 0.194, \quad \frac{\hat{\lambda}_4}{\hat{\lambda}_3}\gamma^2 = 0.277, \]
\[ \frac{\hat{\lambda}_2}{\hat{\lambda}_3}\gamma^2 = 0.174, \quad \frac{\hat{\lambda}_5}{\hat{\lambda}_6}\gamma^2 = 0.736, \]
\[ \frac{\hat{\lambda}_3}{\hat{\lambda}_4}\gamma^2 = 0.666. \]

So, the numbers presented in Table 8.1 reflect quite accurately the predicted rates. The numbers in column 6 are a little too small, though.

The convergence criterion

\[ \max_{1 \leq i \leq p} \| (I - X^{(k)}X^{(k)^*})x_i^{(k-1)} \| \leq \epsilon = 10^{-5} \]

was not satisfied after 50 iteration step.

8.4 Accelerating subspace iteration

Subspace iteration potentially converges very slowly. It can be slow even if it one starts with a subspace that contains all desired solutions! If, e.g., \( x_1^{(0)} \) and \( x_2^{(0)} \) are both elements in \( \mathcal{R}([u_1, u_2]) \), the vectors \( x_i^{(k)}, i = 1, 2, \ldots \), still converge linearly towards \( u_1 \) and \( u_2 \) although they could be readily obtained from the 2 \( \times \) 2 eigenvalue problem,

\[
\begin{bmatrix}
  x_1^{(0)*} \\
  x_2^{(0)*}
\end{bmatrix}
A
\begin{bmatrix}
  x_1^{(0)} \\
  x_2^{(0)}
\end{bmatrix}
y = \lambda y
\]

The following theorem gives hope that the convergence rates can be improved if one proceeds in a suitable way.

**Theorem 8.10** Let \( X \in \mathbb{F}^{n \times p} \) as in Theorem 8.5. Let \( u_i, 1 \leq i \leq p \), be the eigenvectors corresponding to the eigenvalues \( \lambda_1, \ldots, \lambda_p \) of \( A \). Then we have

\[ \min_{x \in \mathcal{R}(X^{(k)})} \sin \angle(u_i, x) \leq c\left(\frac{\lambda_i}{\lambda_{p+1}}\right)^k \]
Proof. In the proof of Theorem 8.5 we have seen that

\[ \mathcal{R}(X^{(k)}) = \mathcal{R}\left(U\left(\begin{pmatrix} I_p \\ S^{(k)} \end{pmatrix}\right)\right), \quad S^{(k)} \in \mathbb{R}^{(n-p) \times p}, \]

where

\[ s^{(k)}_{ij} = s_{ij}\left(\frac{\lambda_j}{\lambda_{p+i}}\right)^k, \quad 1 \leq i \leq n-p, \quad 1 \leq j \leq p. \]

But we have

\[
\min_{x \in \mathcal{R}(X^{(k)})} \sin \angle(u_i, x) \leq \sin \angle\left(u_i, U\left(\begin{pmatrix} I_p \\ S^{(k)} \end{pmatrix}\right)e_i\right),
\]

\[
= (I - u_iu_i^*)U\begin{bmatrix} 0 & \cdots & 0 \\ \vdots & \cdots & \vdots \\ 0 & 1 & 0 \end{bmatrix} / \left\| \begin{pmatrix} I_p \\ S^{(k)} \end{pmatrix} e_i \right\|
\]

\[
\leq (I - u_iu_i^*)\left(u_i + \sum_{j=p+1}^{n} s_{j-p,i}\left(\frac{\lambda_j}{\lambda_{p+j}}\right)^k u_j \right)
\]

\[
= \sqrt{\sum_{j=1}^{n-p} s_{ji}^2}\frac{\lambda_i^2 k}{\lambda_{p+j}} \leq \sqrt{\sum_{j=1}^{n-p} s_{ji}^2} \left(\frac{\lambda_i}{\lambda_{p+j}}\right)^k \frac{\lambda_i^2 k}{\lambda_{p+j}}.
\]

These considerations lead to the idea to complement Algorithm 8.1 by a so-called Rayleigh-Ritz step. Here we give an ‘inverted algorithm’ to compute the smallest eigenvalues and corresponding eigenvectors of a symmetric/Hermitian matrix. For the corresponding nonsymmetric algorithm see [1].

Algorithm 8.2 Subspace or simultaneous inverse iteration combined with Rayleigh-Ritz step

1: Let \( X \in \mathbb{F}^{n \times p} \) with \( X^* X = I_p \);
2: Set \( X^{(0)} := X \);
3: for \( k = 1, 2, \ldots \) do
4: \hspace{1em} Solve \( AZ^{(k)} := X^{(k-1)} \);
5: \hspace{1em} \( Q^{(k)} R^{(k)} := Z^{(k)} \) /* QR factorization of \( Z^{(k)} \) (or modified Gram–Schmidt) */
6: \hspace{1em} \( \hat{H}^{(k)} := Q^{(k)^*} A Q^{(k)} \);
7: \hspace{1em} \( \hat{H}^{(k)} =: F^{(k)} \Theta^{(k)} F^{(k)^*} \) /* Spectral decomposition of \( \hat{H}^{(k)} \in \mathbb{F}^{p \times p} */
8: \hspace{1em} \( X^{(k)} := Q^{(k)} F^{(k)} \).
9: end for

Remark 8.1. The columns \( x^{(k)}_i \) of \( X^{(k)} \) are called Ritz vectors and the eigenvalues \( \psi_1^{(k)} \leq \cdots \leq \psi_p^{(k)} \) in the diagonal of \( \Theta \) are called Ritz values. According to the Rayleigh-
Ritz principle 2.32 we have

\[ \lambda_i \leq \vartheta_i^{(k)} \quad 1 \leq i \leq p, \quad k > 0. \]

The solution of the full eigenvalue problems \( \hat{H}^{(k)}y = \vartheta y \) is solved by the symmetric QR algorithm.

The computation of the matrix \( \hat{H}^{(k)} \) is expensive as matrix-vector products have to be executed. The following considerations simplify matters. We write \( X^{(k)} \) in the form

\[ X^{(k)} = Z^{(k)}G^{(k)}, \quad G^{(k)} \in \mathbb{F}^{p \times p} \text{nonsingular} \]

Because \( X^{(k)} \) must have orthonormal columns we must have

\[ G^{(k)}Z^{(k)*}Z^{(k)}G^{(k)} = I_p. \] (8.18)

Furthermore, the columns of \( Z^{(k)}G^{(k)} \) are the Ritz vectors in \( \mathcal{R}(A^{-k}X) \) of \( A^2 \),

\[ G^{(k)}Z^{(k)*}A^2Z^{(k)}G^{(k)} = \Delta^{(k)-2}, \]

where \( \Delta^{(k)} \) is a diagonal matrix. Using the definition of \( Z^{(k)} \) in Algorithm 8.2 we see that

\[ G^{(k)}X^{(k-1)*}X^{(k-1)}G^{(k)} = G^{(k)}G^{(k)} = \Delta^{(k)-2}, \]

and that \( Y^{(k)} := G^{(k)}\Delta^{(k)} \) is orthogonal. Substituting into (8.18) gives

\[ Y^{(k)*}Z^{(k)*}Z^{(k)}Y^{(k)} = \Delta^{(k)2}. \]

So, the columns of \( Y^{(k)} \) are the normalized eigenvectors of \( H^{(k)} := Z^{(k)*}Z^{(k)} \).

Thus we obtain a second variant of the inverse subspace iteration with Rayleigh-Ritz step.

**Algorithm 8.3** Subspace or simultaneous inverse vector iteration combined with Rayleigh-Ritz step, version 2

1: Let \( X \in \mathbb{F}^{n \times p} \) with \( X^*X = I_p \).
2: Set \( X^{(0)} := X \).
3: for \( k = 1, 2, \ldots \) do
4: \( AZ^{(k)} := X^{(k-1)}; \)
5: \( H^{(k)} := Z^{(k)*}Z^{(k)} \quad /* = X^{(k-1)*}A^{-2}X^{(k-1)} */ \\
6: \( H^{(k)} := Y^{(k)\Delta^{(k)2}}Y^{(k)*} \quad /* \text{Spectral decomposition of } H^{(k)} */ \\
7: \( X^{(k)} = Z^{(k)}Y^{(k)}\Delta^{(k)-1} \quad /* = Z^{(k)}G^{(k)} */ \\
8: end for

**Remark 8.2.** An alternative to Algorithm 8.3 is the subroutine *ritzit*, that has been programmed by Rutishauser [5] in ALGOL, see also [3, p.293].

We are now going to show that the Ritz vectors converge to the eigenvectors, as Theorem 8.10 lets us hope. First we prove

**Lemma 8.11** ([3, p.222]) Let \( y \) be a unit vector and \( \vartheta \in \mathbb{F} \). Let \( \lambda \) be the eigenvalue of \( A \) closest to \( \vartheta \) and let \( u \) be the corresponding eigenvector. Let

\[ \gamma := \min_{\lambda_i(A) \neq \lambda} |\lambda_i(A) - \vartheta| \]
and let $\psi = \angle(y, u)$. Then

$$\sin \psi \leq \frac{\|r(y)\|}{\gamma} := \frac{\|Ay - \vartheta y\|}{\gamma},$$

where $r(y, \vartheta) = Ay - \vartheta y$ plays the role of a residual.

**Proof.** We write $y = u \cos \psi + v \sin \psi$ with $\|v\| = 1$. Then

$$r(y, \vartheta) = Ay - \vartheta y = (A - \vartheta I)u \cos \psi + (A - \vartheta I)v \sin \psi, = (\lambda - \vartheta)u \cos \psi + (A - \vartheta I)v \sin \psi.$$

Because $u^*(A - \vartheta I)v = 0$, Pythagoras' theorem implies

$$\|r(y, \vartheta)\|^2 = (\lambda - \vartheta)^2 \cos^2 \psi + \|(A - \vartheta I)v\|^2 \sin^2 \psi \geq \gamma^2 \|v\|^2 \sin^2 \psi. \quad \blacksquare$$

**Theorem 8.12** ([3, p.298]) Let the assumptions of Theorem 8.5 be satisfied. Let $x^{(k)}_j = x^{(k)} e_j$ be the $j$-th Ritz vector as computed by Algorithm 8.3, and let $y^{(k)}_i = U \left( \begin{array}{c} I_{p(k)} \\ S_{(k)} \end{array} \right) e_i$ (cf. the proof of Theorem 8.5). Then the following inequality holds

$$\sin \angle(x^{(k)}_i, y^{(k)}_i) \leq c \left( \frac{\lambda_i}{\lambda_{p+1}} \right)^k, \quad 1 \leq i \leq p.$$

**Proof.** The columns of $U \left( \begin{array}{c} I_{p(k)} \\ S_{(k)} \end{array} \right)$ form a basis of $R(X^{(k)})$. Therefore, we can write

$$x^{(k)}_i = U \left( \begin{array}{c} I_{p(k)} \\ S_{(k)} \end{array} \right) t_i, \quad t_i \in \mathbb{R}^p.$$

Instead of the special eigenvalue problem

$$X^{(k-1)^*} A^{-2} X^{(k-1)} y = H^{(k)} y = \mu^{-2} y$$

in the orthonormal 'basis' $X^{(k)}$ we consider the equivalent eigenvalue problem

\begin{equation}
(8.19) \quad \left[ I_{p}, S^{(k)*} \right] U A^{-2} U \left( \begin{array}{c} I_{p} \\ S^{(k)} \end{array} \right) t = \mu^{-2} \left[ I_{p}, S^{(k)*} \right] \left( \begin{array}{c} I_{p} \\ S^{(k)} \end{array} \right) t.
\end{equation}

Let $(\mu, t)$ be an eigenpair of (8.19). Then we have

\begin{equation}
(8.20) \quad 0 = \left[ I_{p}, S^{(k)*} \right] U A^{-2} U \left( \begin{array}{c} I_{p} \\ S^{(k)} \end{array} \right) t - \mu^{-2} \left[ I_{p}, S^{(k)*} \right] \left( \begin{array}{c} I_{p} \\ S^{(k)} \end{array} \right) t
= \left( \Lambda_1^{-2} + S^{(k)*} \Lambda_2^{-2} S^{(k)} \right) t - \mu^{-2} \left( I_{p} + S^{(k)*} S^{(k)} \right) t,
= \left( (\Lambda_1^{-2} - \mu^{-2} I) + S^{(k)*} (\Lambda_2^{-2} - \mu^{-2} I) S^{(k)} \right) t
= \left( \Lambda_1^{-2} - \mu^{-2} I \right) + \frac{1}{\lambda_{p+1}} \Lambda_1 H_k \left( \frac{1}{\lambda_{p+1}} \Lambda_1 \right)^k t,
\end{equation}

with

$$H_k = \frac{2k}{\lambda_{p+1}} H^{(0)} S^{(0)*} \Lambda_2^{-k} (\Lambda_2^{-2} - \mu^{-2} I) \Lambda_2^{-k} S^{(0)}.$$
As the largest eigenvalue of $\Lambda_2^{-1}$ is $1/\lambda_{p+1}$, $H_k$ is bounded,

$$\|H_k\| \leq c_1 \quad \forall k > 0.$$ 

Thus,

$$\left( \left( \frac{1}{\lambda_{p+1}} \Lambda_1 \right)^k H_k \left( \frac{1}{\lambda_{p+1}} \Lambda_1 \right)^k \right) t \xrightarrow{\lambda \to \infty} 0.$$ 

Therefore, in (8.20) we can interpret this expression as a perturbation of the diagonal matrix $\Lambda_2^{-2} - \mu^{-2}I$. For sufficiently large $k$ (that may depend on $i$) there is a $\mu_i$ that is close to $\lambda_i$, and a $t_i$ that is close to $e_i$. We now assume that $k$ is so big that

$$|\mu_i^{-2} - \lambda_i^{-1}| \leq \rho := \frac{1}{2} \min_{j \neq i} |\lambda_i^{-2} - \lambda_j^{-2}|$$

such that $\mu_i^{-2}$ is close to $\lambda_i^{-2}$ than to any other $\lambda_j^{-2}$, $j \neq i$.

We now consider the orthonormal ‘basis’

$$B = \left( \begin{array}{c} I_p \\ S(k) \end{array} \right) \left( I_p + S(k)^* S(k) \right)^{-1/2}.$$

If $(\mu_i, t_i)$ is an eigenpair of (8.19) or (8.20), respectively, then \( \left( \mu_i^{-2}, (I_p + S(k)^* S(k))^{1/2} t_i \right) \) is an eigenpair of

(8.21)

\[ B^* A^{-2} B t = \mu^{-2} t. \]

As, for sufficiently large $k$, $(\lambda_i^{-2}, e_i)$ is a good approximation of the eigenpair $(\mu_i^{-2}, t_i)$ of (8.20), then also \( \left( \lambda_i^{-2}, (I_p + S(k)^* S(k))^{1/2} e_i \right) \) is a good approximation to the eigenpair \( \left( \mu_i^{-2}, (I_p + S(k)^* S(k))^{1/2} t_i \right) \) of (8.21). We now apply Lemma 8.11 with

$$\gamma = \rho, \quad \vartheta = \lambda_i^{-2},$$

$$\mathbf{y} = (I_p + S(k)^* S(k))^{1/2} e_i / \left( (I_p + S(k)^* S(k))^{1/2} e_i \right),$$

$$\mathbf{u} = (I_p + S(k)^* S(k))^{1/2} t_i / \left( (I_p + S(k)^* S(k))^{1/2} t_i \right).$$

Now we have

$$\|r(\mathbf{y})\| = \left\| B^* A^{-2*} B - \lambda_i^{-2} I \right\| \left( I_p + S(k)^* S(k) \right)^{1/2} e_i \left\| (I_p + S(k)^* S(k))^{1/2} e_i \right\|$$

$$\leq \left\| (I_p + S(k)^* S(k))^{-1/2} \left[ I_p S(k)^* \right] U A^{-2} U \left( I_p S(k)^* \right) - \frac{1}{\lambda_i^2} \left( I_p + S(k)^* S(k) \right) e_i \right\|$$

$$\leq \left\| (I_p + S(k)^* S(k))^{-1/2} \left[ \Lambda_i^{-2} - \lambda_i^{-2} I + \left( \lambda_{p+1}^{-1} \Lambda_1 \right)^k H_k \left( \lambda_{p+1}^{-1} \Lambda_1 \right)^k \right] e_i \right\|$$

$$\leq \left\| \left( \lambda_{p+1}^{-1} \Lambda_1 \right)^k H_k \left( \lambda_{p+1}^{-1} \Lambda_1 \right)^k e_i \right\|$$

$$\leq \left\| \lambda_{p+1}^{-1} \Lambda_1 \right\|^k \|H_k\| \left\| \left( \lambda_{p+1}^{-1} \Lambda_1 \right)^k e_i \right\| \leq c_1 \left( \frac{\lambda_p}{\lambda_{p+1}} \right)^k \left( \frac{\lambda_i}{\lambda_{p+1}} \right)^k.$$
Then, Lemma 8.11 implies that
\[
\sin \angle(x_i^{(k)}, y_i^{(k)}) = \sin \angle \left( \left( I_p + S^{(k)^*} S^{(k)} \right)^{1/2} t_i, \left( I_p + S^{(k)^*} S^{(k)} \right)^{1/2} e_i \right) \leq \frac{c_1}{\rho} \left( \frac{\lambda_i}{\lambda_{p+1}} \right)^k.
\]

In the proof of Theorem 8.10 we showed that
\[
\angle(u_i, y_i^{(k)}) \leq c_1 \left( \frac{\lambda_i}{\lambda_{p+1}} \right)^k.
\]
In the previous theorem we showed that
\[
\angle(x_i^{(k)}, y_i^{(k)}) \leq c_1 \left( \frac{\lambda_i}{\lambda_{p+1}} \right)^k.
\]
By consequence,
\[
\angle(x_i^{(k)}, u_i) \leq c_2 \left( \frac{\lambda_i}{\lambda_{p+1}} \right)^k
\]
must be true for a constant \(c_2\) independent of \(k\).

As earlier, for the eigenvalues we can show that
\[
|\lambda_i - \lambda_i^{(k)}| \leq c_3 \left( \frac{\lambda_i}{\lambda_{p+1}} \right)^{2k}.
\]

A numerical example

For the previous example that is concerned with the acoustic vibration in the interior of a car the numbers listed in Table 8.2 are obtained. The quotients \(\hat{\lambda}_i^2 / \hat{\lambda}_{p+1}^2\), that determine the convergence behavior of the eigenvalues are
\[
\begin{align*}
(\hat{\lambda}_1 / \hat{\lambda}_6)^2 &= 0.004513, \\
(\hat{\lambda}_2 / \hat{\lambda}_6)^2 &= 0.02357, \\
(\hat{\lambda}_3 / \hat{\lambda}_6)^2 &= 0.1362, \\
(\hat{\lambda}_4 / \hat{\lambda}_6)^2 &= 0.2045, \\
(\hat{\lambda}_5 / \hat{\lambda}_6)^2 &= 0.7321.
\end{align*}
\]
The numbers in the table confirm the improved convergence rate. The convergence rates of the first four eigenvalues have improved considerably. The predicted rates are not clearly visible, but they are approximated quite well. The convergence rate of the fifth eigenvalue has not improved. The convergence of the 5-dimensional subspace \(\mathcal{R}([x_1^{(k)}, \ldots, x_5^{(k)}])\) to the searched space \(\mathcal{R}([u_1, \ldots, u_5])\) has not been accelerated. Its convergence rate is still \(\approx \lambda_5 / \lambda_6\) according to Theorem 8.5.

By means of the Rayleigh-Ritz step we have achieved that the columns \(x_i^{(k)} = x^{(k)}\) converge in an optimal rate to the individual eigenvectors of \(A\).

8.5 Relation between subspace iteration and QR algorithm

The connection between (simultaneous) vector iteration and the QR algorithm has been investigated by Parlett and Poole [4].

Let \(X_0 = I_n\), the \(n \times n\) identity matrix.
### Table 8.2: Example of accelerated basic subspace iteration.

CHAPTER 8. SIMULTANEOUS VECTOR OR SUBSPACE ITERATIONS

Then we have

\[
    AI = A_0 = AX_0 = Y_1 = X_1 R_1 \quad \text{(SVI)}
\]

\[
    A_1 = X_1^* A X_1 = X_1^* X_1 R_1 X_1 = R_1 X_1 \quad \text{(QR)}
\]

\[
    AX_1 = Y_2 = X_2 R_2 \quad \text{(SVI)}
\]

\[
    A_1 = X_1^* Y_2 = X_1^* X_2 R_2 \quad \text{(QR)}
\]

\[
    A_2 = R_2 X_1^* X_2 \quad \text{(QR)}
\]

\[
    = X_2^* X_1^* X_2 R_2 X_1^* X_2 = X_2^* A X_2 \quad \text{(QR)}
\]

More generally, by induction, we have

\[
    AX_k = Y_{k+1} = X_{k+1} R_{k+1} \quad \text{(SVI)}
\]

\[
    A_k = X_k^* A X_k = X_k^* X_k R_{k+1} \quad \text{(QR)}
\]

\[
    A_{k+1} = R_{k+1} X_k^* X_{k+1} \quad \text{(QR)}
\]

\[
    = X_{k+1}^* X_k X_k^* R_{k+1} X_k R_{k+1} = X_{k+1}^* A X_{k+1} \quad \text{(QR)}
\]

Relation to QR: \( Q_1 = X_1, Q_k = X_k^* X_{k+1}. \)

\[
    A^k = A^k X_0 = A^{k-1} A X_0 = A^{k-1} X_1 R_1
\]

\[
    = A^{k-2} A X_1 R_1 = A^{k-2} X_2 R_2 R_1
\]

\[
    \vdots
\]

\[
    = X_k \underbrace{R_k R_{k-1} \cdots R_1}_{U_k} = X_k U_k \quad \text{(QR)}
\]

Because \( U_k \) is upper triangular we can write

\[
    A^k e_1, \ldots, e_p] = X_k U_k e_1, \ldots, e_p] = X_k U_k (\cdot, 1 : p) = X_k (\cdot, 1 : p)
\]

\[
    \begin{bmatrix}
        u_{11} & \cdots & u_{1p} \\
        \vdots & \ddots & \vdots \\
        \vdots & \ddots & u_{pp}
    \end{bmatrix}
\]

This holds for all \( p \). We therefore can interpret the QR algorithm as a nested subspace iteration. There is also a relation to simultaneous inverse vector iteration! Let us assume that \( A \) is invertible. Then we have,\(^1\)

\[
    AX_{k-1} = X_{k-1} A_{k-1} = X_k R_k
\]

\[
    X_k R_k^{-*} = A^{-*} X_{k-1}, \quad R_k^{-*} \text{ is lower triangular}
\]

\[
    X_k R_k^{-*} R_{k-1}^{-*} \cdots R_1^{-*} = (A^{-*})^k X_0
\]

\[
    U_k^{-*}
\]

\(^1\)Notice that \( A^{-*} = (A^{-1})^* = (A^*)^{-1}. \)
8.6. ADDENDUM

Then,

$$X_k[e_\ell, \ldots, e_n] \begin{bmatrix} \bar{u}_{\ell, \ell} & \cdots & \bar{u}_{\ell, n} \\ \vdots & \ddots & \vdots \\ \bar{u}_{n, \ell} & \cdots & \bar{u}_{n, n} \end{bmatrix} = (A^{-*})^k X_0[e_\ell, \ldots, e_n]$$

By consequence, the last \( n - \ell + 1 \) columns of \( X_k \) execute a simultaneous inverse vector iteration. This holds for all \( \ell \). Therefore, the QR algorithm also performs a nested inverse subspace iteration.

8.6 Addendum

Let \( A = H \) be an irreducible Hessenberg matrix and \( W_1 = [w_1, \ldots, w_p] \) be a basis of the \( p \)-th dominant invariant subspace of \( H^* \),

$$H^* W_1 = W_1 S, \quad S \text{ invertible.}$$

Notice that the \( p \)-th dominant invariant subspace is unique if \( |\lambda_p| > |\lambda_{p+1}| \).

Let further \( X_0 = [e_1, \ldots, e_p] \). Then we have the

**Theorem 8.13** \( W_1^* X_0 \) is nonsingular.

**Remark 8.3.** If \( W_1^* X_0 \) is nonsingular then \( W_k^* X_0 \) is nonsingular for all \( k > 0 \). □

**Proof.** If \( W_1^* X_0 \) were singular then there was a vector \( a \in \mathbb{F}^p \) with \( X_0^* W_1 a = 0 \). Thus, \( w = W_1 a \) is orthogonal to \( e_1, \ldots, e_p \). Therefore, the first \( p \) components of \( w \) are zero.

From, \( H^* W_1 = W_1 S \) we have that \( (H^*)^k w \in \mathcal{R}(W_1) \) for all \( k \).

But we have

$$w = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ x \\ \vdots \\ x \end{bmatrix} \quad \text{with} \quad p \text{ zeros}$$

$$H^* w = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ x \\ \vdots \\ x \end{bmatrix} \quad \text{with} \quad p - 1 \text{ zeros}$$

$$\quad (H^*)^k w = \begin{bmatrix} x \\ \vdots \\ x \end{bmatrix}$$

These vectors evidently are linearly independent.

So, we have constructed \( p + 1 \) linearly independent vectors \( w, \ldots, (H^*)^p w \) in the \( p \)-dimensional subspace \( \mathcal{R}(W_1) \). This is a contradiction. □

**Bibliography**

Chapter 9

Krylov subspaces

9.1 Introduction

In the power method or in the inverse vector iteration we computed, up to normalization, sequences of the form

\[ x, Ax, A^2x, \ldots \]

The information available at the \( k \)-th step of the iteration is the single vector \( x^{(k)} = A^k x / \| A^k x \| \). One can pose the question if discarding all the previous information \( \{ x^{(0)}, \ldots, x^{(k-1)} \} \) is not a too big waste of information. This question is not trivial to answer. On one hand there is a big increase of memory requirement, on the other hand exploiting all the information computed up to a certain iteration step can give much better approximations to the searched solution. As an example, let us consider the symmetric matrix

\[
T = \left( \frac{51}{\pi} \right)^2 \begin{bmatrix}
2 & -1 & & & \\
-1 & 2 & -1 & & \\
& \ddots & \ddots & \ddots & \\
& & -1 & 2 & -1 \\
& & & -1 & 2
\end{bmatrix} \in \mathbb{R}^{50 \times 50}.
\]

the lowest eigenvalue of which is around 1. Let us choose \( x = [1, \ldots, 1]^* \) and compute the first three iterates of inverse vector iteration, \( x, T^{-1}x, \) and \( T^{-2}x \). We denote their Rayleigh quotients by \( \rho^{(1)}, \rho^{(2)}, \) and \( \rho^{(3)} \), respectively. The Ritz values \( \vartheta_j^{(k)} \), \( 1 \leq j \leq k \), obtained with the Rayleigh-Ritz procedure with \( K_k(x) = \text{span}(x, T^{-1}x, \ldots, T^{1-k}x) \), \( k = 1, 2, 3 \), are given in Table 9.1. The three smallest eigenvalues of \( T \) are 0.999684, 3.994943, and 8.974416. The approximation errors are thus \( \rho^{(3)} - \lambda_1 \approx 0.000'14 \) and \( \vartheta_1^{(3)} - \lambda_1 \approx 0.000'009 \), which is 15 times smaller.

These results immediately show that the cost of three matrix vector multiplications can be much better exploited than with (inverse) vector iteration. We will consider in this

section a kind of space that is very often used in the iterative solution of linear systems as well as of eigenvalue problems.

9.2 Definition and basic properties

Definition 9.1 The matrix

\[ K^m(x) = K^m(x, A) := [x, Ax, \ldots, A^{(m-1)}x] \in \mathbb{F}^{n \times m} \]

generated by the vector \( x \in \mathbb{F}^n \) is called a Krylov matrix. Its columns span the Krylov (sub)space

\[ \mathcal{K}^m(x) = \mathcal{K}^m(x, A) := \text{span} \{ x, Ax, A^2x, \ldots, A^{(m-1)}x \} = \mathcal{R}(K^m(x)) \subset \mathbb{F}^n. \]

The Arnoldi and Lanczos algorithms are methods to compute an orthonormal basis of the Krylov space. Let

\[ [x, Ax, \ldots, A^{k-1}x] = Q(k)R(k) \]

be the QR factorization of the Krylov matrix \( K^m(x) \). The Ritz values and Ritz vectors of \( A \) in this space are obtained by means of the \( k \times k \) eigenvalue problem

\[ Q(k)^*A Q(k)y = \vartheta(k)y. \]

If \( (\vartheta(j)^{(k)}, y_j) \) is an eigenpair of (9.3) then \( (\vartheta(j)^{(k)}, Q(k)y_j) \) is a Ritz pair of \( A \) in \( K^m(x) \).

The following properties of Krylov spaces are easy to verify \[1\], p.238

1. Scaling. \( K^m(x, A) = K^m(\alpha x, \beta A), \quad \alpha, \beta \neq 0. \)
2. Translation. \( K^m(x, A - \sigma I) = K^m(x, A). \)
3. Change of basis. If \( U \) is unitary then \( UK^m(U^*x, U^*AU) = K^m(x, A). \)

In fact,

\[ K^m(x, A) = [x, Ax, \ldots, A^{(m-1)}x] \]
\[ = U[U^*x, (U^*AU)U^*x, \ldots, (U^*AU)^{m-1}U^*x], \]
\[ = UK^m(U^*x, U^*AU). \]

Notice that the scaling and translation invariance hold only for the Krylov subspace, not for the Krylov matrices.

What is the dimension of \( K^m(x) \)? It is evident that for \( n \times n \) matrices \( A \) the columns of the Krylov matrix \( K^{n+1}(x) \) are linearly dependent. (A subspace of \( \mathbb{F}^n \) cannot have a dimension bigger than \( n \).) On the other hand if \( u \) is an eigenvector corresponding to the eigenvalue \( \lambda \) then \( Au = \lambda u \) and, by consequence, \( \mathcal{K}^2(u) = \text{span} \{ u, Au \} = \text{span} \{ u \} = \mathcal{K}^1(u) \). So, there is a smallest \( m, 1 \leq m \leq n, \) depending on \( x \) such that

\[ \mathcal{K}^1(x) \subset \mathcal{K}^2(x) \subset \cdots \subset \mathcal{K}^m(x) = K^m(x) = \cdots \]

For this number \( m \),

\[ K_{m+1}(x) = [x, Ax, \ldots, A^m x] \in \mathbb{F}^{n \times m+1} \]
has linearly dependant columns, i.e., there is a nonzero vector \( \mathbf{a} \in \mathbb{F}^{m+1} \) such that

\[
K_{m+1}(\mathbf{x})\mathbf{a} = p(A)\mathbf{x} = \mathbf{0}, \quad p(\lambda) = a_0 + a_1\lambda + \cdots + a_m\lambda^m.
\]

The polynomial \( p(\lambda) \) is called the minimal polynomial of \( A \) relativ to \( \mathbf{x} \). By construction, the highest order coefficient \( a_m \neq 0 \).

If \( A \) is diagonalizable, then the degree of the minimal polynomial relativ to \( \mathbf{x} \) has a simple geometric meaning (which does not mean that it is easily checked). Let

\[
\mathbf{x} = \sum_{i=1}^{m} \mathbf{u}_i = [\mathbf{u}_1, \ldots, \mathbf{u}_m] \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix},
\]

where the \( \mathbf{u}_i \) are eigenvectors of \( A \), \( A\mathbf{u}_i = \lambda_i\mathbf{u}_i \), and \( \lambda_i \neq \lambda_j \) for \( i \neq j \). Notice that we have arranged the eigenvectors such that the coefficients in the above sum are all unity.

Now we have

\[
A^k\mathbf{x} = \sum_{i=1}^{m} \lambda_i^k \mathbf{u}_i = [\mathbf{u}_1, \ldots, \mathbf{u}_m] \begin{pmatrix} \lambda_1^k \\ \vdots \\ \lambda_m^k \end{pmatrix},
\]

and, by consequence,

\[
K_j^i(\mathbf{x}) = \begin{bmatrix} 1 & \lambda_1 & \cdots & \lambda_1^{j-1} \\ 1 & \lambda_2 & \cdots & \lambda_2^{j-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \lambda_m & \cdots & \lambda_m^{j-1} \end{bmatrix} \in \mathbb{C}^{m \times j}.
\]

Since matrices of the form

\[
\begin{bmatrix} 1 & \lambda_1 & \cdots & \lambda_1^{j-1} \\ 1 & \lambda_2 & \cdots & \lambda_2^{j-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \lambda_s & \cdots & \lambda_s^{j-1} \end{bmatrix} \in \mathbb{F}^{s \times s}, \quad \lambda_i \neq \lambda_j \text{ for } i \neq j,
\]

so-called Vandermonde matrices, are nonsingular if the \( \lambda_i \) are different (their determinant equals \( \prod_{i \neq j} (\lambda_i - \lambda_j) \)) the Krylov matrices \( K_j^i(\mathbf{x}) \) are nonsingular for \( j \leq m \). Thus for diagonalizable matrices \( A \) we have

\[
\dim K_j^i(\mathbf{x}, A) = \min\{j, m\}
\]

where \( m \) is the number of eigenvectors needed to represent \( \mathbf{x} \). The subspace \( K^m(\mathbf{x}) \) is the smallest invariant space that contains \( \mathbf{x} \).

### 9.3 Polynomial representation of Krylov subspaces

In this section we assume \( A \) to be Hermitian. Let \( \mathbf{s} \in K^j(\mathbf{x}) \). Then

\[
\mathbf{s} = \sum_{i=0}^{j-1} c_i A^i \mathbf{x} = \pi(A)\mathbf{x}, \quad \pi(\xi) = \sum_{i=0}^{j-1} c_i \xi^i.
\]
Let \( P_j \) be the space of polynomials of degree \( \leq j \). Then (9.6) becomes
\[
\mathcal{K}^j(x) = \{ \pi(A)x \mid \pi \in P_{j-1} \}.
\]

Let \( m \) be the smallest index for which \( \mathcal{K}^m(x) = \mathcal{K}^{m+1}(x) \). Then, for \( j \leq m \) the mapping
\[
P_j^{-1} \ni \sum c_i \xi^i \to \sum c_i A^i x \in \mathcal{K}^j(x)
\]
is bijective, while it is only surjective for \( j > m \).

Let \( Q \in \mathbb{F}^{n \times j} \) be a matrix with orthonormal columns that span \( \mathcal{K}^j(x) \), and let \( A' = Q^*AQ \). The spectral decomposition
\[
A'X' = X'\Theta, \quad X'^*X' = I, \quad \Theta = \text{diag}(\vartheta_1, \ldots, \vartheta_j),
\]
of \( A' \) provides the Ritz values of \( A \) in \( \mathcal{K}^j(x) \). The columns \( y_i \) of \( Y = QX' \) are the Ritz vectors.

By construction the Ritz vectors are mutually orthogonal. Furthermore,
\[
Ay_i - \vartheta_i y_i \perp \mathcal{K}^j(x)
\]
because
\[
Q^*(AQx'_i - Qx'_i\vartheta_i) = Q^*AQx'_i - x'_i\vartheta_i = A'x'_i - x'_i\vartheta_i = 0.
\]

It is easy to represent a vector in \( \mathcal{K}^j(x) \) that is orthogonal to \( y_i \).

**Lemma 9.2** Let \( (\vartheta_i, y_i) \), \( 1 \leq i \leq j \) be Ritz values and Ritz vectors of \( A \) in \( \mathcal{K}^j(x) \), \( j \leq m \). Let \( \omega \in P_{j-1} \). Then
\[
\omega(A)x \perp y_k \iff \omega(\vartheta_k) = 0.
\]

**Proof.** "\( \iff \)" Let first \( \omega \in P_j \) with \( \omega(x) = (x - \vartheta_k)\pi(x) \), \( \pi \in P_{j-1} \). Then
\[
y_k^*\omega(A)x = y_k^*(A - \vartheta_k I)\pi(A)x, \quad \text{here we use that } A = A^*
\]
\[
=(Ay_k - \vartheta_k y_k)^*\pi(A)x \overset{(9.8)}{=} 0.
\]

"\( \implies \)" Let \( \mathcal{S}_k \subset \mathcal{K}^j(x) \) be defined by
\[
\mathcal{S}_k := (A - \vartheta_k I)\mathcal{K}^{j-1}(x) = \{ \tau(A)x \mid \tau \in P_{j-1}, \tau(\vartheta_k) = 0 \}.
\]

Each polynomial \( \tau \) in the definition of \( \mathcal{S}_k \) has the form \( \tau(\vartheta_k) = (x - \vartheta_k)\psi(x) \), \( \psi \in P_{j-2} \). Therefore, \( \dim(\mathcal{S}_k) = \dim(P_{j-2}) = j - 1 \). As the dimension of a subspace of \( \mathcal{K}^j(x) \) that is orthogonal to \( y_k \) is \( j - 1 \), it must coincide with \( \mathcal{S}_k \).

Next we define the polynomials
\[
\mu(\xi) := \prod_{i=1}^j (\xi - \vartheta_i) \in P_j, \quad \pi_k(\xi) := \frac{\mu(\xi)}{(\xi - \vartheta_k)} = \prod_{i=1}^j (\xi - \vartheta_i) \in P_{j-1}.
\]

Then the Ritz vector \( y_k \) can be represented in the form
\[
y_k = \frac{\pi_k(A)x}{\|\pi_k(A)x\|},
\]
9.3. POLYNOMIAL REPRESENTATION OF KRYLOV SUBSPACES

as $\pi_k(\xi) = 0$ for all $\vartheta_i, i \neq k$. According to Lemma 9.2 $\pi_k(A)x$ is perpendicular to all $y_i$ with $i \neq k$. Further,

\begin{equation}
(9.12) \quad \beta_j := \left\| \mu(A)x \right\| = \min \{ \left\| \omega(A)x \right\| \mid \omega \in \mathbb{P}_j \text{ monic} \}.
\end{equation}

(A polynomial in $\mathbb{P}_j$ is monic if its highest coefficients $a_j = 1$.) By the first part of Lemma 9.2 $\mu(A)x \in \mathcal{K}^{j+1}(x)$ is orthogonal to $\mathcal{K}^j(x)$. As each monic $\omega \in \mathbb{P}_j$ can be written in the form $\omega(\xi) = \mu(\xi) + \psi(\xi), \quad \psi \in \mathbb{P}_{j-1}$, we have

\[ \left\| \omega(A)x \right\|^2 = \left\| \mu(A)x \right\|^2 + \left\| \psi(A)x \right\|^2, \]

as $\psi(A)x \in \mathcal{K}^j(x)$. Because of property (9.12) $\mu$ is called the minimal polynomial of $x$ of degree $j$. (In (9.5) we constructed the minimal polynomial of degree $m$ in which case $\beta_m = 0$.)

Let $u_1, \ldots, u_m$ be the eigenvectors of $A$ corresponding to $\lambda_1 < \cdots < \lambda_m$ that span $\mathcal{K}^m(x)$. We collect the first $i$ of them in the matrix $U_i := \begin{bmatrix} u_1 & \cdots & u_i \end{bmatrix}$. Let $\|x\| = 1$. Let $\varphi := \angle(x,u_i)$ and $\psi := \angle(x,U_iU_i^*x) \leq \varphi$. (Remember that $U_iU_i^*x$ is the orthogonal projection of $x$ on $\mathcal{R}(U_i)$.)

Let

\[ g := \frac{U_iU_i^*x}{\|U_iU_i^*x\|} \quad \text{and} \quad h := \frac{(I - U_iU_i^*)x}{\|(I - U_iU_i^*)x\|}. \]

Then we have

\[ \|U_iU_i^*x\| = \cos \psi, \quad \|(I - U_iU_i^*)x\| = \sin \psi. \]

The following Lemma will be used for the estimation of the difference $\vartheta_i^{(j)} - \lambda_i$ of the desired eigenvalue and its approximation from the Krylov subspace.

**Lemma 9.3** ([1, p.241]) For each $\pi \in \mathbb{P}_{j-1}$ and each $i \leq j \leq m$ the Rayleigh quotient

\[ \rho(\pi(A)x; A - \lambda_i I) = \frac{(\pi(A)x)^*(A - \lambda_i I)(\pi(A)x)}{\|\pi(A)x\|^2} = \rho(\pi(A)x; A) - \lambda_i \]

satisfies the inequality

\begin{equation}
(9.13) \quad \rho(\pi(A)x; A - \lambda_i I) \leq (\lambda_m - \lambda_i) \left[ \frac{\sin \psi}{\cos \varphi} \frac{\|\pi(A)h\|}{\pi(\lambda_i)} \right]^2.
\end{equation}

**Proof.** With the definitions of $g$ and $h$ from above we have

\[ x = U_iU_i^*x + (I - U_iU_i^*)x = \cos \psi \ g + \sin \psi \ h. \]

which is an orthogonal decomposition. As $\mathcal{R}(U_i)$ is invariant under $A$,

\[ s := \pi(A)x = \cos \psi \ \pi(A)g + \sin \psi \ \pi(A)h \]

is an orthogonal decomposition of $s$. Thus,

\begin{equation}
(9.14) \quad \rho(\pi(A)x; A - \lambda_i I) = \frac{\cos^2 \psi \ g^*(A - \lambda_i I)\pi^2(A)g + \sin^2 \psi \ h^*(A - \lambda_i I)\pi^2(A)h}{\|\pi(A)x\|^2}.
\end{equation}

Since $\lambda_1 < \lambda_2 < \cdots < \lambda_m$, we have
CHAPTER 9. KRYLOV SUBSPACES

(i) \( \mathbf{v}^*(A - \lambda_i I)\mathbf{v} \leq 0 \) for all \( \mathbf{v} \in \mathcal{R}(U_i) \),

(ii) \( \mathbf{w}^*(A - \lambda_i I)\mathbf{w} \leq (\lambda_m - \lambda_i)\|\mathbf{w}\|^2 \) for all \( \mathbf{w} \in \mathcal{R}(U_i) \).

Setting \( \mathbf{v} = \pi(A)\mathbf{g} \) and \( \mathbf{w} = \pi(A)\mathbf{h} \) we obtain from (9.14)

\[
\rho(s; A - \lambda_i I) \leq \sin^2 \psi (\lambda_m - \lambda_i) \frac{\|\pi(A)\mathbf{h}\|^2}{\|\pi(A)\mathbf{x}\|^2}.
\]

With

\[
\|\mathbf{s}\|^2 = \|\pi(A)\mathbf{x}\|^2 = \sum_{l=1}^{m} \pi^2(\lambda_l) (\mathbf{x}^* \mathbf{u}_l)^2 \geq \pi^2(\lambda_i) \cos^2 \varphi
\]

we obtain the claim.

\[\blacksquare\]

### 9.4 Error bounds of Saad

The error bounds to be presented have been published by Saad [2]. We follow the presentation in Parlett [1]. The error bounds for \( \vartheta^{(j)}_i - \lambda_i \) are obtained by carefully selecting the polynomial \( \pi \) in Lemma 9.3. Of course we would like \( \pi(A) \) to be as small as possible and \( \pi(\lambda_i) \) to be as large as possible. First, by the definition of \( \mathbf{h} \), we have

\[
\|\pi(A)\mathbf{h}\|^2 = \frac{\|\pi(A)(I - U_i U_i^*)\mathbf{x}\|^2}{\|I - U_i U_i^*\mathbf{x}\|^2} = \frac{\|\pi(A) \sum_{l=i+1}^{m} (\mathbf{u}_l^* \mathbf{x}) \mathbf{u}_l\|^2}{\|\sum_{l=i+1}^{m} (\mathbf{u}_l^* \mathbf{x}) \mathbf{u}_l\|^2} \leq \max_{i \leq l \leq m} \pi^2(\lambda_l) \leq \max_{\lambda_{i+1} \leq \lambda \leq \lambda_m} \pi^2(\lambda).
\]

The last inequality is important! In this step the search of a maximum in a few selected points \( (\lambda_{i+1}, \ldots, \lambda_m) \) is replaced by a search of a maximum in a \textit{whole interval} containing these points. Notice that \( \lambda_i \) is \textit{outside} of this interval. Among all polynomials of a given degree that take a given fixed value \( \pi(\lambda_i) \) the Chebyshev polynomial have the smallest maximum. As \( \vartheta^{(j)}_i \) is a Ritz value, we know from the monotonicity principle 2.32 that

\[0 \leq \vartheta^{(j)}_i - \lambda_i.\]

Further, from the definition of \( \vartheta^{(j)}_i \) (as an eigenvalue of \( A \) in the subspace \( \mathcal{K}^j(x) \)),

\[\vartheta^{(j)}_i - \lambda_i \leq \rho(s, A - \lambda_i I) \quad \text{provided that } s \perp y_l, \quad 1 \leq l \leq i - 1.\]

According to Lemma 9.2 \( s = \pi(A)x \) is orthogonal on \( y_1, \ldots, y_{i-1} \), if \( \pi \) has the form

\[\pi(\xi) = (\xi - \vartheta^{(j)}_1) \cdots (\xi - \vartheta^{(j)}_{i-1}) \omega(\xi), \quad \omega \in \mathbb{P}_{i-1} .\]

With this choice of \( \pi \) we get

\[
\frac{\|\pi(A)\mathbf{h}\|}{\pi(\lambda_i)} \leq \frac{\|\mathbf{A} - \vartheta^{(j)}_1 I \| \cdots \| \mathbf{A} - \vartheta^{(j)}_{i-1} I \| \| \omega(A)\mathbf{h}\|}{\|\lambda_i - \vartheta^{(j)}_1\| \cdots \|\lambda_i - \vartheta^{(j)}_{i-1}\| \|\omega(\lambda_i)\|} \leq \prod_{l=1}^{i-1} \frac{\lambda_m - \vartheta^{(j)}_i}{\lambda_i - \vartheta^{(j)}_i} \max_{\lambda_{i+1} \leq \lambda \leq \lambda_m} \frac{\omega(\lambda)}{\omega(\lambda_i)} .
\]
This expression should be as small as possible. Now we have
\[
\min_{\omega} \max_{\lambda_{i+1} \leq \lambda \leq \lambda_m} |\omega(\lambda)| = \frac{\max_{\lambda_{i+1} \leq \lambda \leq \lambda_m} T_{j-i}(\lambda; [\lambda_{i+1}, \lambda_m])}{T_{j-i}(\lambda; [\lambda_{i+1}, \lambda_m])} = \frac{1}{T_{j-i}(\lambda; [\lambda_{i+1}, \lambda_m])} = \frac{1}{T_{j-i}(1+2\gamma)}, \quad \gamma = \frac{\lambda_{i+1} - \lambda_i}{\lambda_m - \lambda_{i+1}}.
\]

\(T_{j-i}(1+2\gamma)\) is the value of the Chebyshev polynomial corresponding to the normal interval \([-1, 1]\). The point \(1+2\gamma\) is obtained if the affine transformation

\[|\lambda_{i+1}, \lambda_m| \ni \lambda \rightarrow \frac{2\lambda - \lambda_{i+1} - \lambda_m}{\lambda_i - \lambda_{i+1}} \in [-1, 1]\]

is applied to \(\lambda_i\).

Thus we have proved the first part of the following

**Theorem 9.4** [2] Let \(\varphi^{(j)}_1, \ldots, \varphi^{(j)}_j\) be the Ritz values of \(A\) in \(K^j(x)\) and let \((\lambda_l, u_l), l = 1, \ldots, m\), be the eigenpairs of \(A\) (in \(K^m(x)\)). Then for all \(i \leq j\) we have

\[
(9.15) \quad 0 \leq \varphi^{(j)}_i - \lambda_i \leq (\lambda_m - \lambda_i) \left[ \sin \varphi \cdot \frac{\pi}{\cos \varphi} \cdot \frac{\prod_{l=1}^{i-1} \frac{\lambda_m - \varphi^{(j)}_l}{\lambda_l - \varphi^{(j)}_l}}{T_{j-i}(1+2\gamma)} \right]^2, \quad \gamma = \frac{\lambda_{i+1} - \lambda_i}{\lambda_m - \lambda_{i+1}},
\]

and

\[
(9.16) \quad \tan \angle(u_i, \text{projektion of } u_i \text{ on } K^j) \leq \frac{\sin \psi}{\cos \varphi} \cdot \frac{\prod_{l=1}^{i-1} \frac{\lambda_m - \lambda_l}{\lambda_l - \lambda_i}}{T_{j-i}(1+2\gamma)}.
\]

**Proof.** For proving the second part of the Theorem we write

\[x = g \cos \angle(x, U_{i-1}U_i^*x) + u_i \cos \angle(x, u_i) + h \sin \angle(x, U_iU_i^*x).\]

We choose \(\pi\) such that \(\pi(\lambda_1) = \cdots = \pi(\lambda_{i-1}) = 0\). Then

\[s = \pi(A)x = \pi(\lambda_i)u_i \cos \varphi + \pi(A)h \sin \psi\]

is an orthogonal decomposition of \(s\). By consequence,

\[
\tan \angle(s, u_i) = \frac{\sin \psi}{\cos \varphi} \cdot \frac{\|\pi(A)h\|}{\|\pi(\lambda_i)\|}.
\]

The rest is similar as above.

**Remark 9.1.** Theorem 9.4 does not give bounds for the angle between \(\angle(u_i, y_i)\), an angle that would be more interesting than the abstract angle between \(u_i\) and its projection on \(K^j(x)\). It is possible however to show that [1, p. 246]

\[
\sin \angle(u_i, y_i) \leq \sqrt{1 + \frac{\beta^2_j}{\gamma_i^{(j)^2}}} \sin \angle(u_i, \text{projektion of } u_i \text{ onto } K^j)
\]
$\beta_j$ is the number that appeared earlier in the discussion after Lemma 9.2, and

$$\gamma_i^{(j)} = \min_{s \neq i} |\lambda_i - \vartheta_s^{(j)}|$$

Theorem 9.4 can easily be rewritten to give error bounds for $\lambda_m - \vartheta_j^{(j)}$, $\lambda_{m-1} - \vartheta_{j-1}^{(j)}$, etc.

We see from this Theorem that the eigenvalues at the beginning and at the end of the spectrum are approximated the quickest. For the first eigenvalue the bound (9.15) simplifies a little,

$$0 \leq \vartheta_1^{(j)} - \lambda_1 \leq (\lambda_m - \lambda_1) \frac{\tan^2 \varphi_1}{T_{j-1}(1 + 2\gamma_1)^2}, \quad \gamma_1 = \frac{\lambda_2 - \lambda_1}{\lambda_m - \lambda_2}, \quad \varphi_1 = \angle(x, u_1).$$

Analogously, for the largest eigenvalue we have

$$0 \leq \lambda_m - \vartheta_j^{(j)} \leq (\lambda_m - \lambda_1) \frac{1}{T_{j-1}(1 + 2\gamma_m)^2},$$

with

$$\gamma_m = \frac{\lambda_m - \lambda_{m-1}}{\lambda_{m-1} - \lambda_1}, \quad \text{and} \quad \cos \varphi_m = x^* u_m.$$

If the Lanczos algorithmus is applied with $(A - \sigma I)^{-1}$ as with the shifted and inverted vector iteration then we form Krylov spaces $K_j^{(x, (A - \sigma I)^{-1})}$. Here the largest eigenvalues are $\hat{\lambda}_1 \geq \hat{\lambda}_2 \geq \cdots \geq \hat{\lambda}_j$, $\hat{\lambda}_i = \lambda_i - \sigma$.

Eq. (9.18) then becomes

$$0 \leq \frac{1}{\hat{\lambda}_1} - \frac{1}{\hat{\vartheta}_j^{(j)}} \leq (\frac{1}{\hat{\lambda}_1} - \frac{1}{\hat{\lambda}_j}) \frac{\tan^2 \varphi_1}{T_{j-1}(1 + 2\gamma_1)^2}, \quad \hat{\gamma}_1 = \frac{1}{\hat{\lambda}_1} - \frac{1}{\hat{\lambda}_2}.$$ 

Now, we have

$$1 + 2\hat{\gamma}_1 = 2(1 + \hat{\gamma}_1) - 1 = 2 \left( \frac{1}{\lambda_1} - \frac{1}{\lambda_j} \right) - 1 = 2 \frac{\hat{\lambda}_2}{\lambda_1} \left( \frac{1 - \frac{\hat{\lambda}_2}{\lambda_2}}{1 - \frac{\hat{\lambda}_2}{\lambda_1}} \right) - 1 \geq 2 \frac{\hat{\lambda}_2}{\lambda_1} - 1 > 1.$$

Since $|T_{j-1}(\xi)|$ grows rapidly and monotonically outside $[-1, 1]$ we have

$$T_{j-1}(1 + 2\hat{\gamma}_1) \geq T_{j-1}(2 \frac{\hat{\lambda}_2}{\lambda_1} - 1),$$

and thus

$$\frac{1}{\hat{\lambda}_1} - \frac{1}{\hat{\vartheta}_1^{(j)}} \leq c_1 \left( \frac{1}{T_{j-1}(2 \frac{\hat{\lambda}_2}{\lambda_1} - 1)} \right)^2$$

With the simple inverse vector iteration we had

$$\frac{1}{\hat{\lambda}_1} - \frac{1}{\hat{\vartheta}_1^{(j)}} \leq c_2 \left( \frac{\hat{\lambda}_1}{\lambda_2} \right)^{2(j-1)}$$
In Table 9.2 the numbers

\[
\left( \frac{1}{T_{j-1}(2\hat{\lambda}_2/\hat{\lambda}_1 - 1)} \right)^2
\]

are compared with

\[
\left( \frac{\hat{\lambda}_1}{\hat{\lambda}_2} \right)^{2(j-1)}
\]

for \( \hat{\lambda}_2/\hat{\lambda}_1 = 2, 1.1, 1.01 \). If this ratio is large both methods quickly provide the desired results. If however the ratio tends to 1 then a method that computes the eigenvalues by means of Ritz values of Krylov spaces shows an acceptable convergence behaviour whereas vector iteration hardly improves with \( j \). Remember that \( j \) is the number of matrix-vector multiplications have been executed, or, with the shift-and-invert spectral transformation, how many systems of equations have been solved.

Bibliography

Chapter 10

Arnoldi and Lanczos algorithms

10.1 An orthonormal basis for the Krylov space \( K_j(x) \)

The natural basis of the Krylov subspace \( K_j(x) = K_j(x, A) \) is evidently \( \{x, Ax, \ldots, A^{j-1}x\} \). Remember that the vectors \( A^kx \) converge to the direction of the eigenvector corresponding to the largest eigenvalue (in modulus) of \( A \). Thus, this basis tends to be badly conditioned with increasing dimension \( j \). Therefore, the straightforward procedure, the Gram–Schmidt orthogonalization process, is applied to the basis vectors in their natural order.

Suppose that \( \{q_1, \ldots, q_i\} \) is the orthonormal basis for \( K_i(x) \), where \( i \leq j \). We construct the vector \( q_{j+1} \) by first orthogonalizing \( A^jx \) against \( q_1, \ldots, q_j \),

\[
(10.1) \quad y_j := A^jx - \sum_{i=1}^{j} q_i q_i^* A^jx,
\]

and then normalizing the resulting vector,

\[
(10.2) \quad q_{j+1} = y_j / \|y_j\|.
\]

Then \( \{q_1, \ldots, q_{j+1}\} \) is an orthonormal basis of \( K_{j+1}(x) \), called in general the Arnoldi basis or, if the matrix \( A \) is real symmetric or Hermitian, the Lanczos basis. The vectors \( q_i \) are called Arnoldi vectors or Lanczos vectors, respectively, see \([6, 1]\).

The vector \( q_{j+1} \) can be computed in a more economical way since

\[
K_{j+1}(x, A) = \mathcal{R}\left(\{x, Ax, \ldots, A^jx\}\right),
\]

\[
= \mathcal{R}\left(\{q_1, Aq_1, \ldots, A^j q_1\}\right), \quad (q_1 = x / ||x||),
\]

\[
= \mathcal{R}\left(\{q_1, Aq_1, \ldots, A^j q_1\}\right), \quad (Aq_1 = \alpha q_1 + \beta q_2, \, \beta \neq 0),
\]

\[
= \mathcal{R}\left(\{q_1, Aq_1, \ldots, A^j q_1\}\right), \quad (Aq_1 = \alpha q_1 + \beta q_2, A(\alpha q_1 + \beta q_2), \ldots, A^{j-1}(\alpha q_1 + \beta q_2))
\]

\[
= \mathcal{R}\left(\{q_1, Aq_1, \ldots, A^j q_1\}\right),
\]

\[
= \mathcal{R}\left(\{q_1, q_2, Aq_2, \ldots, A^{j-1} q_2\}\right),
\]

\[
= \mathcal{R}\left(\{q_1, q_2, \ldots, A^{j-1} q_2\}\right).
\]

So, instead of orthogonalizing \( A^j q_1 \) against \( q_1, \ldots, q_j \), we can orthogonalize \( Aq_j \) against \( q_1, \ldots, q_j \) to obtain \( q_{j+1} \). The component \( r_j \) of \( Aq_j \) orthogonal to \( q_1, \ldots, q_j \) is given by

\[
(10.3) \quad r_j = Aq_j - \sum_{i=1}^{j} q_i (q_i^* Aq_j).
\]
CHAPTER 10. ARNOLDI AND LANCZOS ALGORITHMS

If \( r_j = 0 \) then the procedure stops which means that we have found an invariant subspace, namely \( \text{span}\{q_1, \ldots, q_j\} \). If \( \|r_j\| > 0 \) we obtain \( q_{j+1} \) by normalizing,

\[
q_{j+1} = \frac{r_j}{\|r_j\|}.
\]

Since, \( q_{j+1} \) and \( r_j \) are aligned, we have

\[
q_j^* r_j = \|r_j\| \quad (10.3) \Rightarrow q_j^* A q_j.
\]

The last equation holds since \( q_{j+1} \) (by construction) is orthogonal to all the previous Arnoldi vectors. Let

\[
h_{ij} = q_i^* A q_j.
\]

Then, \((10.3)–(10.5)\) can be written as

\[
A q_j = \sum_{i=1}^{j+1} q_i h_{ij}.
\]

We collect the procedure in Algorithm 10.1

**Algorithm 10.1 The Arnoldi algorithm for the computation of an orthonormal basis of a Krylov space**

1: Let \( A \in \mathbb{F}^{n \times n} \). This algorithm computes an orthonormal basis for \( K^k(x) \).
2: \( q_1 = x/\|x\|_2 \);
3: for \( j = 1, \ldots \) do
4: \( \mathbf{r} := A q_j \);
5: for \( i = 1, \ldots, j \) do /* Gram-Schmidt orthogonalization */
6: \( h_{ij} := q_i^* \mathbf{r}, \mathbf{r} := \mathbf{r} - q_i h_{ij} \);
7: end for
8: \( h_{j+1,j} := \|\mathbf{r}\| \);
9: if \( h_{j+1,j} = 0 \) then /* Found an invariant subspace */
10: return \( (q_1, \ldots, q_j, H \in \mathbb{F}^{j \times j}) \)
11: end if
12: \( q_{j+1} = \mathbf{r}/h_{j+1,j} \);
13: end for
14: return \( (q_1, \ldots, q_{k+1}, H \in \mathbb{F}^{k+1 \times k}) \)

The Arnoldi algorithm returns if \( h_{j+1,j} = 0 \), in which case \( j \) is the degree of the minimal polynomial of \( A \) relative to \( x \), cf. \((9.5)\). This algorithm costs \( k \) matrix-vector multiplications, \( n^2/2 + O(n) \) inner products, and the same number of \( \text{axpy} \)'s.

Defining \( Q_k = [q_1, \ldots, q_k] \), equation \((10.6)\) can be collected for \( j = 1, \ldots, k \),

\[
AQ_k = Q_k H_k + [\underbrace{0, \ldots, 0}_{k-1 \text{ times}}, q_{k+1} h_{k+1,k}]
\]

Equation \((10.7)\) is called \textbf{Arnoldi relation}. The construction of the Arnoldi vectors is expensive. Most of all, each iteration step becomes more costly as the number of vectors against which \( \mathbf{r} \) has to be orthogonalized increases. Therefore, algorithms based on the Arnoldi relation like GMRES or the Arnoldi algorithm itself are restarted. This in general means that the algorithm is repeated with a initial vector that is extracted from previous invocation of the algorithm.
10.2 Arnoldi algorithm with explicit restarts

Algorithm 10.1 stops if $h_{m+1,m} = 0$, i.e., if it has found an invariant subspace. The vectors \{q_1, \ldots, q_m\} then form an invariant subspace of $A$.

\[ AQ_m = Q_m H_m, \quad Q_m = [q_1, \ldots, q_m]. \]

The eigenvalues of $H_m$ are eigenvalues of $A$ as well and the Ritz vectors are eigenvectors of $A$.

In general, we cannot afford to store the vectors $q_1, \ldots, q_m$ because of limited memory space. Furthermore, the algorithmic complexity increases linearly in the iteration number $j$. The orthogonalization would cost $2nm^2$ floating point operations.

Often it is possible to extract good approximate eigenvectors from a Krylov space of small dimension. We have seen, that in particular the extremal eigenvalues and corresponding eigenvectors are very well approximated after a few iteration steps. So, if only a small number of eigenpairs is desired, it is usually sufficient to get away with Krylov space of much smaller dimension than $m$.

Exploiting the Arnoldi relation (10.7) we can get cheap estimates for the eigenvalue/eigenvector residuals. Let $u_i^{(k)} = Q_k s_i^{(k)}$ be a Ritz vector with Ritz value $\vartheta_i^{(k)}$. Then

\[ A u_i^{(k)} - \vartheta_i^{(k)} u_i^{(k)} = A Q_k s_i^{(k)} - \vartheta_i^{(k)} Q_k s_i^{(k)} = (A Q_k - Q_k H_k) s_i^{(k)} = h_{k+1,k} q_{k+1} e_k^* s_i^{(k)}. \]

Therefore,

\[ \| (A - \vartheta_i^{(k)} I) u_i^{(k)} \|_2 = h_{k+1,k} | e_k^* s_i^{(k)}|. \]

The residual norm is equal to the last component of $s_i^{(k)}$ multiplied by $h_{k+1,k}$ (which is positive by construction). These residual norms are not always indicative of actual errors in $\lambda_i^{(k)}$, but they can be helpful in deriving stopping procedures.

We now consider an algorithm for computing some of the extremal eigenvalues of a non-Hermitian matrix. The algorithm proceeds by computing one eigenvector or rather Schur vector at the time. For each of them an individual Arnoldi procedure is employed. Let us assume that we have already computed $k - 1$ Schur vectors $u_1, \ldots, u_{k-1}$. To compute $u_k$ we force the iterates in the Arnoldi process (the Arnoldi vectors) to be orthogonal to $U_{k-1}$ where $U_{k-1} = [u_1, \ldots, u_{k-1}]$. So, we work essentially with the matrix

\[ (I - U_{k-1}^* U_{k-1}) A \]

that has $k - 1$ eigenvalues zero which we of course neglect.

The procedure is given in Algorithm 10.2. The Schur vectors $u_1, \ldots, u_{k-1}$ are kept in the search space, while the Krylov space is formed with the next approximate Schur vector. The search space thus is

\[ \text{span}\{u_1, \ldots, u_{k-1}, u_k, A u_k, \ldots, A^{m-k} u_k\}. \]

In Algorithm 10.2 the basis vectors are denoted $v_j$ with $v_j = u_j$ for $j < k$. The vectors $v_k, \ldots, v_m$ form an orthonormal basis of $\text{span}\{u_k, A u_k, \ldots, A^{m-k} u_k\}$.

The matrix $H_m$ for $k = 2$ has the structure

\[ H_m = \begin{bmatrix} * & * & * & * & * & * & * \\ * & * & * & * & * & * & * \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \end{bmatrix} \]
Algorithm 10.2 Explicitly restarted Arnoldi algorithm

1: Let $A \in \mathbb{F}^{n \times n}$. This algorithm computes the $n_{ev}$ largest eigenvalues of $A$ together with the corresponding Schur vectors.
2: Set $k = 1$.
3: \textbf{loop}
4: \hspace{1em} \textbf{for} $j = k, \ldots, m$ \textbf{do} /* Execute $m - k$ steps of Arnoldi */
5: \hspace{1em} $r := Aq_j$;
6: \hspace{1em} \textbf{for} $i = 1, \ldots, j$ \textbf{do}
7: \hspace{2em} $h_{ij} := q_i^*r$, $r := r - q_i h_{ij}$;
8: \hspace{1em} \textbf{end for}
9: \hspace{1em} $h_{j+1,j} := \|r\|$;
10: \hspace{1em} $q_{j+1} = r/h_{j+1,j}$;
11: \hspace{1em} \textbf{end for}
12: Compute approximate eigenvector of $A$ associated with $\lambda_k$ and the corresponding residual norm estimate $\rho_k$ according to (10.8).
13: Orthogonalize this eigenvector (Ritz vector) against all previous $v_j$ to get the approximate Schur vector $u_k$. Set $v_k := u_k$.
14: \hspace{1em} \textbf{if} $\rho_k$ is small enough \textbf{then} /* accept eigenvalue */
15: \hspace{2em} \textbf{for} $i = 1, \ldots, k$ \textbf{do}
16: \hspace{3em} $h_{ik} := v_i^*A v_k$;
17: \hspace{2em} \textbf{end for}
18: \hspace{1em} Set $k := k + 1$.
19: \hspace{1em} \textbf{if} $k \geq n_{ev}$ \textbf{then}
20: \hspace{2em} \textbf{return} $(v_1, \ldots, v_k, H \in \mathbb{F}^{k \times k})$
21: \hspace{1em} \textbf{end if}
22: \hspace{1em} \textbf{end if}
23: \textbf{end loop}

where the block in the lower right corresponds to the Arnoldi process for the Krylov space $\mathcal{K}_{m-k}(u_k, (I - U_{k-1}U_{k-1}^*) A)$.

This algorithm needs at most $m$ basis vectors. As soon as the dimension of the search space reaches $m$ the Arnoldi iteration is \textbf{restarted} with the best approximation as the initial vector. The Schur vectors that have already converged are \textbf{locked} or \textbf{deflated}.

### 10.3 The Lanczos basis

We have seen that the Lanczos basis is formally constructed in the same way as the Arnoldi basis, however with a Hermitian matrix. It deserves a special name for the simplifications that the symmetry entails.

By multiplying (10.7) with $Q_k^*$ from the left we get

$$Q_k^* A Q_k = Q_k^* Q_k H_k = H_k.$$ (10.9)

If $A$ is Hermitian, then so is $H_k$. This means that $H_k$ is \textit{tridiagonal}. To emphasize this matrix structure, we call this tridiagonal matrix $T_k$. Due to symmetry, equation (10.3) simplifies considerably,

$$r_j = A q_j - q_j (q_j^* A q_j) - q_{j-1} (q_{j-1}^* A q_j) = A q_j - \alpha_j q_j - \beta_{j-1} q_{j-1}.$$ (10.10)
Similarly as earlier, we premultiply (10.10) by \( q_{j+1}^* \) to get

\[
\|r_j\| = q_{j+1}^* r_j = q_{j+1}^* (Aq_j - \alpha_j q_j - \beta_{j-1} q_{j-1})
\]

\[
= q_{j+1}^* Aq_j = \beta_j.
\]

From this it follows that \( \beta_j \in \mathbb{R} \). Therefore,

\[
(10.11) \quad \beta_j q_{j+1} = r_j, \quad \beta_j = \|r_j\|.
\]

Collecting (10.10)–(10.11) yields

\[
(10.12) \quad Aq_j = \beta_{j-1} q_{j-1} + \alpha_j q_j + \beta_j q_{j+1}.
\]

Gathering these equations for \( j = 1, \ldots, k \) we get

\[
(10.13) \quad AQ_k = Q_k \begin{pmatrix}
\alpha_1 & \beta_1 & \alpha_2 & \beta_2 & \cdots & \beta_{k-1} \\
\beta_1 & \alpha_2 & \beta_2 & \alpha_3 & \cdots & \beta_{k-1} \\
& \beta_2 & \alpha_3 & \cdots & \beta_{k-1} & \alpha_k \\
& & \ddots & \cdots & \beta_{k-1} & \alpha_k \\
& & & \ddots & \beta_{k-1} & \alpha_k \\
& & & & \ddots & \beta_{k-1} \\
& & & & & \beta_{k-1} \\
\end{pmatrix} + \beta_k [0, \ldots, 0, q_{k+1}].
\]

\( T_k \in \mathbb{R}^{k \times k} \) is real symmetric. Equation (10.13) is called Lanczos relation. Pictorially, this is

\[
A_k Q_k = Q_k T_k + O
\]

The Lanczos algorithm is summarized in Algorithm 10.3. In this algorithm just the three vectors \( q, r, \) and \( v \) are employed. In the \( j \)-th iteration step (line 8) \( q \) is assigned \( q_j \) and \( v \) stores \( q_{j-1} \). \( r \) stores first (line 9) \( Aq_j - \beta_{j-1} q_{j-1} \). Later (step 11), when \( \alpha_j \) is available, it stores \( r_j = Aq_j - \beta_{j-1} q_{j-1} - \alpha_j q_j \). In the computation of \( \alpha_j \) the fact is exploited that \( q_j^* q_{j-1} = 0 \) whence

\[
\alpha_j = q_j^* Aq_j = q_j^* (Aq_j - \beta_{j-1} q_{j-1}).
\]

In each traversal of the \( j \)-loop a column is appended to the matrix \( Q_{j-1} \) to become \( Q_j \). If the Lanczos vectors are not desired this statement can be omitted. The Lanczos vectors are required to compute the eigenvectors of \( A \). Algorithm 10.3 returns when \( j = m \), where \( m \) is the degree of the minimal polynomial of \( A \) relative to \( \lambda \). \( b_m = 0 \) implies

\[
(10.14) \quad AQ_m = Q_m T_m.
\]
CHAPTER 10. ARNOLDI AND LANCZOS ALGORITHMS

Algorithm 10.3 Basic Lanczos algorithm for the computation of an orthonormal basis for of the Krylov space $K_m(x)$

1: Let $A \in \mathbb{F}^{n \times n}$ be Hermitian. This algorithm computes the Lanczos relation (10.13), i.e., an orthonormal basis $Q_m = [q_1, \ldots, q_m]$ for $K_m(x)$ where $m$ is the smallest index such that $K_m(x) = K_{m+1}(x)$, and (the nontrivial elements of) the tridiagonal matrix $T_m$.

2: $q := x/\|x\|; \quad Q_1 = [q]$;
3: $r := Ax$;
4: $\alpha_1 := q^*r$;
5: $r := r - \alpha_1 q$;
6: $\beta_1 := \|r\|$;
7: for $j = 2, 3, \ldots$ do
8: $v := q$; $q := r/\beta_{j-1}$; $Q_j := [Q_{j-1}, q]$;
9: $r := Ax - \beta_{j-1}v$;
10: $\alpha_j := q^*r$;
11: $r := r - \alpha_j q$;
12: $\beta_j := \|r\|$;
13: if $\beta_j = 0$ then
14: return $(Q \in \mathbb{F}^{n \times j}; \alpha_1, \ldots, \alpha_j; \beta_1, \ldots, \beta_{j-1})$
15: end if
16: end for

Let $(\lambda_i, s_i)$ be an eigenpair of $T_m$,

\[
T_m s_i^{(m)} = \vartheta_i^{(m)} s_i^{(m)}.
\]

Then,

\[
AQ_m s_i^{(m)} = Q_m T_m s_i^{(m)} = \vartheta_i^{(m)} Q_m s_i^{(m)}.
\]

So, the eigenvalues of $T_m$ are also eigenvalues of $A$. The eigenvector of $A$ corresponding to the eigenvalue $\vartheta_i$ is

\[
y_i = Q_m s_i^{(m)} = [q_1, \ldots, q_m] s_i^{(m)} = \sum_{j=1}^{m} q_j s_j^{(m)}.
\]

The cost of a single iteration step of Algorithm 10.3 does not depend on the index of the iteration! In a single iteration step we have to execute a matrix-vector multiplication and $7n$ further floating point operations.

Remark 10.1. In certain very big applications the Lanczos vectors cannot be stored for reasons of limited memory. In this situation, the Lanczos algorithm is executed without building the matrix $Q$. When the desired eigenvalues and Ritz vectors have been determined from (10.15) the Lanczos algorithm is repeated and the desired eigenvectors are accumulated on the fly using (10.17).

10.4 The Lanczos process as an iterative method

The Lanczos Algorithm 10.3 essentially determines an invariant Krylov subspace $K_m(x)$ of $\mathbb{F}^n$. More precisely, it constructs an orthonormal basis $\{q_1, \ldots, q_m\}$ of $K_m(x)$. The
projection of $A$ onto this space is a Hessenberg or even a real tridiagonal matrix if $A$ is Hermitian.

We have seen in section 9.4 that the eigenvalues at the end of the spectrum are approximated very quickly in Krylov spaces. Therefore, only a very few iteration steps may be required to get those eigenvalues (and corresponding eigenvectors) within the desired accuracy, i.e., $|\vartheta_i - \lambda_j|$ may be tiny for $j \ll m$.

The Ritz values $\vartheta_i^{(j)}$ are the eigenvalues of the tridiagonal matrices $T_j$ that are generated element by element in the course of the Lanczos algorithm. They can be computed efficiently by, e.g., the tridiagonal QR algorithm in $O(j^2)$ flops. The cost for computing the eigenvalues of $T_j$ are in general negligible compared with the cost for forming $AQ_j$. But how can the error $|\vartheta_i^{(j)} - \lambda_i|$ be estimated? We will adapt the following more general lemma to this end.

Lemma 10.1 (Eigenvalue inclusion of Krylov–Bogoliubov [5, 7, p.69]) Let $A \in \mathbb{F}^{n \times n}$ be Hermitian. Let $\vartheta \in \mathbb{R}$ and $x \in \mathbb{F}^n$ with $x \neq 0$ be arbitrary. Set $\tau := \| (A - \vartheta I) x \| / \| x \|$. Then there is an eigenvalue of $A$ in the interval $[\vartheta - \tau, \vartheta + \tau]$.

Proof. Let

$$A = U \Lambda U^* = \sum_{i=1}^{n} \lambda_i u_i u_i^*$$

be the spectral decomposition of $A$. Then,

$$(A - \vartheta I) x = \sum_{i=1}^{n} (\lambda_i u_i u_i^* - \vartheta u_i u_i^*) x = \sum_{i=1}^{n} (\lambda_i - \vartheta) (u_i^* x) u_i.$$

Taking norms, we obtain

$$\| (A - \vartheta I) x \|^2 = \sum_{i=1}^{n} |\lambda_i - \vartheta|^2 |u_i^* x|^2 \geq |\lambda_k - \vartheta|^2 \sum_{i=1}^{n} |u_i^* x|^2 = |\lambda_k - \vartheta|^2 \| x \|^2,$$

where $\lambda_k$ is the eigenvalue closest to $\vartheta$, i.e., $|\lambda_k - \vartheta| \leq |\lambda_i - \vartheta|$ for all $i$. □

We want to apply this Lemma to the case where the vector is a Ritz vector $y_i^{(j)}$ corresponding to the Ritz value $\tau = \vartheta_i^{(j)}$ as obtained in the $j$-th step of the Lanczos algorithm. Then,

$$y_i^{(j)} = Q_j s_i^{(j)}, \quad T_j s_i^{(j)} = \vartheta_i^{(j)} s_i^{(j)}.$$

Thus, by employing the Lanczos relation (10.13),

$$\| A y_i^{(j)} - \vartheta_i^{(j)} y_i^{(j)} \| = \| AQ_j s_i^{(j)} - \vartheta_i^{(j)} Q_j s_i^{(j)} \|$$

$$= \| (AQ_j - Q_j T_j) s_i^{(j)} \|$$

$$= |\beta_j| s_{j+1}^{(j)} = |\beta_j| |e_j^{(j)} s_i^{(j)}| = |\beta_j| |s_{ji}^{(j)}|.$$}

$s_{ji}^{(j)}$ is the $j$-th, i.e., the last element of the eigenvector matrix $S_j$ of $T_j$,

$$T_j S_j = S_j \Theta_j, \quad \Theta_j = \text{diag} (\vartheta_1^{(j)}, \ldots, \vartheta_j^{(j)}).$$

According to Lemma 10.1 there is an eigenvalue $\lambda$ of $A$ such that

$$|\lambda - \vartheta_i^{(j)}| \leq |\beta_j| s_{ji}.$$
Thus, it is possible to get good eigenvalue approximations even if $\beta_j$ is not small! Further, we know that [7, §11.7]

\begin{equation}
\sin \angle(y_i^{(j)}, z) \leq \beta_j \frac{|s_{ji}|}{\gamma},
\end{equation}

where $z$ is the eigenvector corresponding to $\lambda$ in (10.18) and $\gamma$ is the gap between $\lambda$ and the next eigenvalue $\neq \lambda$ of $A$. In an actual computation, $\gamma$ is not known. Parlett suggests to replace $\gamma$ by the distance of $\vartheta_i^{(j)}$ to the next $\vartheta_j^{(k)}$, $k \neq i$. Because the $\vartheta_j^{(k)}$ converge to eigenvalues of $A$ this substitution will give a reasonable number, at least in the limit.

In order to use the estimate (10.18) we need to compute all eigenvalues of $T_j$ and the last row of $S_j$. It is possible and in fact straightforward to compute this row without the rest of $S_j$. The algorithm, a simple modification of the tridiagonal QR algorithm, has been introduced by Golub and Welsch [3] in connection with the computation of interpolation points and weights in Gaussian integration.

**A numerical example**

This numerical example is intended to show that the implementation of the Lanczos algorithm is not as simple as it seems from the previous. Let

$A = \text{diag}(0, 1, 2, 3, 4, 100000)$

and

$x = (1, 1, 1, 1, 1)^T$.

The diagonal matrix $A$ has six simple eigenvalues and $x$ has a non-vanishing component in the direction of each eigenspace. Thus, the Lanczos algorithm should stop after $m = n = 6$ iteration steps with the complete Lanczos relation. Up to rounding error, we expect that $\beta_6 = 0$ and that the eigenvalues of $T_6$ are identical with those of $A$. Let’s see what happens if Algorithm 10.3 is applied with these input data. In the sequel we present the numbers that we obtained with a MATLAB implementation of this algorithm.

\[
\begin{align*}
\text{\textbf{\textit{\(j = 1\)}}} & \quad \alpha_1 = 16668.3333333334, \quad \beta_1 = 37267.05429136513. \\
\text{\textbf{\textit{\(j = 2\)}}} & \quad \alpha_2 = 8333.66652666384, \quad \beta_2 = 3.464101610531258. \\
\end{align*}
\]

The diagonal of the eigenvalue matrix $\Theta_2$ is:

$\text{diag}(\Theta_2) = (1.999959999195565, 99999.9989999799)^T$.

The last row of $\beta_2 S_2$ is

$\beta_2 S_2, = (1.4142135626139063, 162277655014521)$.

The matrix of Ritz vectors $Y_2 = Q_2 S_2$ is

\[
\begin{pmatrix}
-0.4472 & -2.0000 \cdot 10^{-05} \\
-0.4472 & -9.9998 \cdot 10^{-06} \\
-0.4472 & 4.0002 \cdot 10^{-10} \\
-0.4472 & 1.0001 \cdot 10^{-05} \\
-0.4472 & 2.0001 \cdot 10^{-05} \\
4.4723 \cdot 10^{-10} & 1.0000
\end{pmatrix}
\]
10.4. THE LANCZOS PROCESS AS AN ITERATIVE METHOD

\[ j = 3 \]

\[ \alpha_3 = 2.000112002245340 \quad \beta_3 = 1.183215957295906. \]

The diagonal of the eigenvalue matrix is

\[ \text{diag}(\Theta_3) = (0.585772437575532, 3.414199561869119, 99999.99999999999)^T. \]

The largest eigenvalue has converged already. This is not surprising as \( \lambda_2/\lambda_1 = 4 \cdot 10^{-5} \). With simple vector iteration the eigenvalues would converge with the factor \( \lambda_2/\lambda_1 = 4 \cdot 10^{-5} \).

The last row of \( \beta_3 S_3 \) is

\[ \beta_3 S_3 = (0.8366523355001995, 0.8366577176165411, 3.741732220526109 \cdot 10^{-05}). \]

The matrix of Ritz vectors \( Y_3 = Q_3 S_3 \) is

\[
\begin{pmatrix}
0.76345 & 0.13099 & 2.0000 \cdot 10^{-10} \\
0.53983 & -0.09263 & -1.0001 \cdot 10^{-10} \\
0.31622 & -0.31623 & -2.0001 \cdot 10^{-10} \\
0.09262 & -0.53984 & -1.0000 \cdot 10^{-10} \\
-0.13098 & -0.76344 & 2.0001 \cdot 10^{-10} \\
-1.5864 \cdot 10^{-13} & -1.5851 \cdot 10^{-13} & 1.00000
\end{pmatrix}
\]

The largest element (in modulus) of \( Y_3^T Y_3 \) is \( 3 \cdot 10^{-12} \).

The Ritz vectors (and thus the Lanczos vectors \( \phi_i \)) are mutually orthogonal up to rounding error.

\[ j = 4 \]

\[ \alpha_4 = 2.000007428756856 \quad \beta_4 = 1.014186947306611. \]

The diagonal of the eigenvalue matrix is

\[ \text{diag}(\Theta_4) = \begin{pmatrix}
0.1560868732577987 \\
1.99998789840119 \\
3.84390456066355 \\
99999.99999999999
\end{pmatrix}. \]

The last row of \( \beta_4 S_4 \) is

\[ \beta_4 S_4 = (0.46017, -0.77785, -0.46018, 3.7949 \cdot 10^{-10}). \]

The matrix of Ritz vectors \( Y_4 = Q_4 S_4 \) is

\[
\begin{pmatrix}
-0.82515 & 0.069476 & -0.40834 & -0.18249 \\
-0.034415 & 0.41262 & -0.40834 & -0.18243 \\
0.37812 & 0.37781 & -0.40834 & -0.18236 \\
0.41256 & -0.034834 & -0.40834 & -0.18230 \\
0.069022 & -0.82520 & -0.40834 & -0.18223 \\
-1.3202 \cdot 10^{-04} & 1.3211 \cdot 10^{-04} & -0.40777 & 0.91308
\end{pmatrix}
\]

The largest element (in modulus) of \( Y_4^T Y_4 \) is \( 2 \cdot 10^{-8} \).

We have \( \beta_4 S_4 \approx 4 \cdot 10^{-10} \). So, according to our previous estimates (\( \vartheta_4, \mathbf{y}_4 \)), \( \mathbf{y}_4 = Y_4 \mathbf{e}_4 \) is a very good approximation for an eigenpair of \( A \). This is in fact the case.

Notice that \( Y_4^T Y_4 \) has off diagonal elements of the order \( 10^{-8} \). These elements are in the last row/column of \( Y_4^T Y_4 \). This means that all Ritz vectors have a small but not negligible component in the direction of the ‘largest’ Ritz vector.
\[ j = 5 \]

\[ \alpha_5 = 2.363169101109444 \quad \beta_5 = 190.5668098726485. \]

The diagonal of the eigenvalue matrix is

\[
\text{diag}(\Theta_5) = \begin{pmatrix}
0.04749223464478182 \\
1.413262891598485 \\
2.894172742223630 \\
4.008220660846780 \\
9.99999999999999 \cdot 10^4
\end{pmatrix}.
\]

The last row of \( \beta_5 S_5 \) is

\[
\beta_5 S_5 : = \begin{pmatrix}
-43.570 - 111.38134.0963.4957.2320 \cdot 10^{-13}
\end{pmatrix}.
\]

The matrix of Ritz vectors \( Y_5 \) is

\[
\begin{pmatrix}
-0.98779 & -0.08486 & 0.049886 & 0.017056 & -1.1424 \cdot 10^{-17} \\
-0.14188 & 0.83594 & -0.21957 & -0.065468 & -7.2361 \cdot 10^{-18} \\
0.063480 & 0.54001 & 0.42660 & 0.089943 & -8.0207 \cdot 10^{-18} \\
-0.010200 & -0.048519 & 0.87582 & -0.043531 & -5.1980 \cdot 10^{-18} \\
-0.0014168 & -0.0055339 & 0.015585 & -0.99269 & -1.6128 \cdot 10^{-17} \\
4.3570 \cdot 10^{-4} & 0.0011138 & -0.0013409 & -6.3497 \cdot 10^{-4} & 1.0000
\end{pmatrix}
\]

Evidently, the last column of \( Y_5 \) is an excellent eigenvector approximation. Notice, however, that all Ritz vectors have a relatively large \((\sim 10^{-4})\) last component. This, gives rise to quite large off-diagonal elements of \( Y_5^T Y_5 - I_5 = \)

\[
\begin{pmatrix}
2.220 \cdot 10^{-16} & -1.587 \cdot 10^{-16} & -3.430 \cdot 10^{-12} & -7.890 \cdot 10^{-9} & -7.780 \cdot 10^{-4} \\
-1.587 \cdot 10^{-16} & -1.110 \cdot 10^{-16} & 1.283 \cdot 10^{-12} & -1.764 \cdot 10^{-8} & -1.740 \cdot 10^{-3} \\
-3.430 \cdot 10^{-12} & 1.283 \cdot 10^{-12} & 0 & 5.680 \cdot 10^{-17} & -6.027 \cdot 10^{-8} \\
-7.890 \cdot 10^{-9} & -1.764 \cdot 10^{-8} & 5.680 \cdot 10^{-17} & -2.220 \cdot 10^{-16} & 4.187 \cdot 10^{-16} \\
-7.780 \cdot 10^{-4} & -1.740 \cdot 10^{-3} & -6.027 \cdot 10^{-8} & 4.187 \cdot 10^{-16} & -1.110 \cdot 10^{-16}
\end{pmatrix}
\]

Similarly as with \( j = 4 \), the first four Ritz vectors satisfy the orthogonality condition very well. But they are not perpendicular to the last Ritz vector.

\[ j = 6 \]

\[ \alpha_6 = 99998.06336906151 \quad \beta_6 = 396.6622037049789 \]

The diagonal of the eigenvalue matrix is

\[
\text{diag}(\Theta_6) = \begin{pmatrix}
0.0248348385326367 \\
1.273835519171372 \\
2.726145019098232 \\
3.975161765440400 \\
9.999842654044850 \cdot 10^{-4} \\
1.000000000000000 \cdot 10^{-5}
\end{pmatrix}.
\]

The eigenvalues are not the exact ones, as was to be expected. We even have two copies of the largest eigenvalue of \( A \) in \( \Theta_6 \)! The last row of \( \beta_6 S_6 \) is

\[
\beta_6 S_6 : = \begin{pmatrix}
-0.20603, 0.49322, 0.49323, 0.20604, 396.66, -8.6152 \cdot 10^{-15}
\end{pmatrix}.
\]
although theory predicts that $\beta_6 = 0$. The sixth entry of $\beta_6S_6$ is very small, which means that the sixth Ritz value and the corresponding Ritz vector are good approximations to an eigenpair of $A$. In fact, eigenvalue and eigenvector are accurate to machine precision.

$\beta_5s_{6,5}$ does not predict the fifth column of $Y_6$ to be a good eigenvector approximation, although the angle between the fifth and sixth column of $Y_6$ is less than $10^{-3}$. The last two columns of $Y_6$ are

$$
\begin{pmatrix}
-4.7409 \cdot 10^{-4} & -3.3578 \cdot 10^{-17} \\
1.8964 \cdot 10^{-3} & -5.3735 \cdot 10^{-17} \\
-2.8447 \cdot 10^{-3} & -7.0931 \cdot 10^{-17} \\
1.8965 \cdot 10^{-3} & -6.7074 \cdot 10^{-17} \\
-4.7414 \cdot 10^{-4} & -4.9289 \cdot 10^{-17} \\
-0.99999 & 1.0000
\end{pmatrix}.
$$

As $\beta_6 \neq 0$ one could continue the Lanczos process and compute ever larger tridiagonal matrices. If one proceeds in this way one obtains multiple copies of certain eigenvalues $[2, 2]$. The corresponding values $\beta_j s_{j,i}^{(j)}$ will be tiny. The corresponding Ritz vectors will be ‘almost’ linearly dependent.

From this numerical example we see that the problem of the Lanczos algorithm consists in the loss of orthogonality among Ritz vectors which is a consequence of the loss of orthogonality among Lanczos vectors, since $Y_j = Q_j S_j$ and $S_j$ is unitary (up to roundoff).

To verify this diagnosis, we rerun the Lanczos algorithm with complete reorthogonalization. This procedure amounts to the Arnoldi algorithm $10.1$. It can be accomplished by modifying line 11 in the Lanczos algorithm $10.3$, see Algorithm $10.4$.

**Algorithm 10.4 Lanczos algorithm with full reorthogonalization**

11: $r := r - \alpha_j q$; \hspace{1cm} $r := r - Q(Q^* r)$;

Of course, the cost of the algorithm increases considerably. The $j$-th step of the algorithm requires now a matrix-vector multiplication and $(2j + O(1))n$ floating point operations.

**A numerical example [continued]**

With matrix and initial vector as before Algorithm $10.4$ gives the following numbers.

**$j = 1$**

$\alpha_1 = 16668.33333368$, \hspace{1cm} $\beta_1 = 37267.05429136513$.

**$j = 2$**

$\alpha_2 = 83333.66652666384$, \hspace{1cm} $\beta_2 = 3.46410161053258$.

The diagonal of the eigenvalue matrix $\Theta_2$ is:

$$\text{diag}(\Theta_2) = (1.999959999195565, 99999.99989999799)^T.$$

**$j = 3$**

$\alpha_3 = 2.000112002240894$, \hspace{1cm} $\beta_3 = 1.183215957295905$

The diagonal of the eigenvalue matrix is

$$\text{diag}(\Theta_3) = (0.5857724375677908, 3.414199561859357, 100000.0000000000)^T.$$
\[ j = 4 \]
\[
\alpha_4 = 2.00007428719501 \quad \beta_4 = 1.014185105707661
\]
\[
\text{diag}(\Theta_4) = \begin{pmatrix}
0.1560868732475296 \\
1.99998789917647 \\
3.84390465596084 \\
99999.9999999999
\end{pmatrix}
\]
The largest off-diagonal element of \(|Y^T Y_4|\) is about \(2 \cdot 10^{-16}\)

\[ j = 5 \]
\[
\alpha_5 = 2.000009143040107 \quad \beta_5 = 0.7559289460488005
\]
\[
\text{diag}(\Theta_5) = \begin{pmatrix}
0.0248356875408838 \\
1.273840384543175 \\
2.726149884630423 \\
3.975162614480485 \\
10000.00000000000
\end{pmatrix}
\]
The Ritz vectors are \(Y_5 = \)
\[
\begin{pmatrix}
-9.91 \cdot 10^{-01} & -4.62 \cdot 10^{-02} & 2.16 \cdot 10^{-02} & -6.19 \cdot 10^{-03} & -4.41 \cdot 10^{-18} \\
-1.01 \cdot 10^{-01} & 8.61 \cdot 10^{-01} & -1.36 \cdot 10^{-01} & -3.31 \cdot 10^{-02} & 1.12 \cdot 10^{-17} \\
7.48 \cdot 10^{-02} & 4.87 \cdot 10^{-01} & 4.87 \cdot 10^{-01} & -7.48 \cdot 10^{-02} & -5.89 \cdot 10^{-18} \\
-3.31 \cdot 10^{-02} & -1.36 \cdot 10^{-01} & 8.61 \cdot 10^{-01} & -1.01 \cdot 10^{-01} & 1.07 \cdot 10^{-17} \\
6.19 \cdot 10^{-03} & 2.16 \cdot 10^{-02} & -4.62 \cdot 10^{-02} & -9.91 \cdot 10^{-01} & 1.13 \cdot 10^{-17} \\
5.98 \cdot 10^{-18} & 1.58 \cdot 10^{-17} & -3.39 \cdot 10^{-17} & -5.96 \cdot 10^{-17} & 1.000000000000000
\end{pmatrix}
\]
Largest off-diagonal element of \(|Y^T Y_5|\) is about \(10^{-16}\) The last row of \(\beta_5 S_5\) is
\[
\beta_5 S_5 = (-0.20603, -0.49322, 0.49322, 0.20603, 2.8687 \cdot 10^{-15}).
\]

\[ j = 6 \]
\[
\alpha_6 = 2.000011428799386 \quad \beta_6 = 4.178550866749342 \cdot 10^{-28}
\]
\[
\text{diag}(\Theta_6) = \begin{pmatrix}
7.950307079340746 \cdot 10^{-13} \\
1.000000000000002 \\
2.000000000000021 \\
3.000000000000088 \\
4.000000000001099 \\
9.999999999999999 \cdot 10^{-4}
\end{pmatrix}
\]
The Ritz vectors are very accurate. \(Y_6\) is almost the identity matrix are 1.0. The largest off diagonal element of \(Y^T Y_6\) is about \(10^{-16}\). Finally,
\[
\beta_6 S_6 = (4.99 \cdot 10^{-29}, -2.00 \cdot 10^{-28}, 3.00 \cdot 10^{-28}, -2.00 \cdot 10^{-28}, 5.00 \cdot 10^{-29}, 1.20 \cdot 10^{-47}).
\]
10.5. AN ERROR ANALYSIS OF THE UNMODIFIED LANCZOS ALGORITHM

With a much enlarged effort we have obtained the desired result. Thus, the loss of orthogonality among the Lanczos vectors can be prevented by the explicit reorthogonalization against *all* previous Lanczos vectors. This amounts to applying the Arnoldi algorithm. In the sequel we want to better understand when the loss of orthogonality actually happens.

**10.5 An error analysis of the unmodified Lanczos algorithm**

When the quantities $Q_j, T_j, r_j, etc.$, are computed numerically by using the Lanczos algorithm, they can deviate greatly from their theoretical counterparts. However, despite this gross deviation from the exact model, it nevertheless delivers fully accurate Ritz value and Ritz vector approximations.

In this section $Q_j, T_j, r_j$ etc. denote the *numerically computed* values and not their theoretical counterparts. So, instead of the Lanczos relation (10.13) we write

\[(10.20) \quad AQ_j - Q_jT_j = r_j e_j^* + F_j \]

where the matrix $F_j$ accounts for errors due to roundoff. Similarly, we write

\[(10.21) \quad I_j - Q_j^*Q_j = C_j^* + \Delta_j + C_j, \]

where $\Delta_j$ is a diagonal matrix and $C_j$ is a *strictly* upper triangular matrix (with zero diagonal). Thus, $C_j^* + \Delta_j + C_j$ indicates the deviation of the Lanczos vectors from orthogonality.

We make the following assumptions

1. The tridiagonal eigenvalue problem can be solved exactly, i.e.,

\[(10.22) \quad T_j = S_j \Theta_j S_j^*, \quad S_j^* = S_j^{-1}, \quad \Theta_j = \text{diag}(\vartheta_1, \ldots, \vartheta_j). \]

2. The orthogonality of the Lanczos vectors holds *locally*, i.e.,

\[(10.23) \quad q_{i+1}^* q_i = 0, \quad i = 1, \ldots, j-1, \quad \text{and} \quad r_j^* q_i = 0. \]

3. Furthermore,

\[(10.24) \quad \|q_i\| = 1. \]

So, we assume that the computations that we actually perform (like orthogonalizations or solving the eigenvalue problem) are accurate. These assumptions imply that $\Delta_j = O$ and $c_{i,i+1}^{(j)} = 0$ for $i = 1, \ldots, j-1$.

We premultiply (10.20) by $Q_j^*$ and obtain

\[(10.25) \quad Q_j^* A Q_j - Q_j^* Q_j T_j = Q_j^* F_j + Q_j^* F_j\]

In order to eliminate $A$ we subtract from this equation its transposed,

\[(10.26) \quad Q_j^* r_j e_j^* - e_j r_j^* Q_j = -Q_j^* Q_j T_j + T_j Q_j^* Q_j + Q_j^* F_j - F_j^* Q_j, \]

\[= (I - Q_j^* Q_j) T_j - T_j (I - Q_j^* Q_j) + Q_j^* F_j - F_j^* Q_j, \]

\[= (C_j + C_j^*) T_j - T_j (C_j + C_j^*) + Q_j^* F_j - F_j^* Q_j, \]

\[(10.21) \quad = (C_j T_j - T_j C_j) + (C_j^* T_j - T_j C_j^*) - F_j^* Q_j + Q_j^* F_j. \]
Now, from this equation we subtract again its transposed, such that

\[ F_j^*Q_j - Q_j^*F_j = -K_j^* + K_j, \]

where \( K_j \) is an upper triangular matrix with zero diagonal. Thus, (10.25) has the form

\[
\begin{pmatrix}
O & \times \\
\times & \vdots & \times \\
\times & \ldots & \times
\end{pmatrix}
= \begin{pmatrix}
0 & C_jT_j - T_jC_j \\
C_j^*T_j - T_jC_j^* & 0 \\
-K_j^* & 0
\end{pmatrix}
\]

First \( j - 1 \) components of \( r_j^*Q_j \).

As the last component of \( Q_j^*r_j \) vanishes, we can treat these triangular matrices separately. For the upper triangular matrices we have

\[ Q_j^*r_j e_j^* = C_jT_j - T_jC_j + K_j. \]

Multiplication by \( s_i^* \) and \( s_i \), respectively, from left and right gives

\[
\begin{align*}
& \begin{pmatrix}
s_i^*Q_j^* \\
y_i^* \beta_j q_{j+1} \\
s_{ji}^* \end{pmatrix} \begin{pmatrix}
r_j \\
e_j s_i \\
1
\end{pmatrix} = s_i^* (C_jT_j - T_jC_j)s_i + s_i^* K_j s_i.
\end{align*}
\]

Let \( G_j := S_j^* K_j S_i \). Then we have

\[ (10.27) \quad \beta_j s_{ji} y_i^* q_{j+1} = s_{ji} y_i^* r_j = s_{ji}^* C_j s_i \partial_i - \partial_i s_{ji}^* C_j s_i + g_{ii}^{(j)} = g_{ii}^{(j)}. \]

We now multiply (10.25) with \( s_i^* \) from the left and with \( s_k^* \) from the right. As \( Q_j s_i = y_i \), we have

\[ y_i^* Ay_k - y_i^* y_k \partial k = y_i^* r_j e_j^* s_k + s_i^* Q_j^* F_j s_k. \]

Now, from this equation we subtract again its transposed, such that \( A \) is eliminated,

\[
\begin{align*}
\begin{pmatrix}
\frac{g_{jj}^{(j)}}{s_{ji}} \\
\frac{g_{kk}^{(j)}}{s_{ji}} \\
\frac{g_{ikk}^{(j)}}{s_{ji}}
\end{pmatrix} - \begin{pmatrix}
\frac{g_{jj}^{(j)}}{s_{ji}} \\
\frac{g_{kk}^{(j)}}{s_{ji}} \\
\frac{g_{ikk}^{(j)}}{s_{ji}}
\end{pmatrix} \\
+ \frac{1}{2} (s_i^* Q_j^* F_j s_k + s_k^* F_j^* Q_j s_i) - \frac{1}{2} (s_i^* Q_j^* F_j s_i + s_i^* F_j^* Q_j s_k)
\end{align*}
\]

\[ = g_{ii}^{(j)} \frac{g_{jj}^{(j)}}{s_{ji}} - g_{kk}^{(j)} \frac{g_{kk}^{(j)}}{s_{ji}} - (g_{kk}^{(j)} - g_{ii}^{(j)}). \]

Thus we have proved

**Theorem 10.2** (Paige, see [7, p.266]) *With the above notations we have*

\[ (10.28) \quad y_i^{(j)*} q_{j+1} = \frac{g_{ii}^{(j)}}{\beta_j s_{ji}^{(j)}}. \]

\[ (10.29) \quad (\vartheta_i^{(j)} - \vartheta_k^{(j)}) y_i^{(j)*} y_k^{(j)} = g_{ii}^{(j)} \frac{s_{jk}}{s_{ji}} - g_{kk}^{(j)} \frac{s_{jk}}{s_{ji}} - (g_{kk}^{(j)} - g_{ii}^{(j)}). \]
10.6. PARTIAL REORTHOGONALIZATION

We can interpret these equations in the following way.

- From numerical experiments it is known that equation (10.20) is always satisfied to machine precision. Thus, \( \|F_j\| \approx \varepsilon \|A\| \). Therefore, \( \|G_j\| \approx \varepsilon \|A\| \), and, in particular, \( \|q^{(j)}_k\| \approx \varepsilon \|A\| \).

- We see from (10.28) that \( |y^{(j)}_i q_{j+1}| \) becomes large if \( \beta_j s^{(j)}_{ji} \) becomes small, i.e., if the Ritz vector \( y^{(j)}_i \) is a good approximation of the corresponding eigenvector. Thus, each new Lanczos vector has a significant component in the direction of converged ('good') Ritz vectors.

As a consequence: convergence \( \iff \) loss of orthogonality

- Let \( |s^{(j)}_{ji}| \ll |s^{(j)}_{jk}| \), i.e., \( y^{(j)}_i \) is a good Ritz vector in contrast to \( y^{(j)}_k \) that is a 'bad' Ritz vector. Then in the first term on the right of (10.29) two small \( (O(\varepsilon)) \) quantities counteract each other such that the right hand side in (10.29) becomes large, \( O(1) \). If the corresponding Ritz values are well separated, \( |\vartheta_i - \vartheta_k| = O(1) \), then \( |y^{(j)}_i y^{(j)}_k| \gg \varepsilon \). So, in this case also 'bad' Ritz vectors have a significant component in the direction of the 'good' Ritz vectors.

- If \( |\vartheta_i - \vartheta_k| = O(\varepsilon) \) and both \( s^{(j)}_{ji} \) and \( s^{(j)}_{jk} \) are of \( O(\varepsilon) \) the \( s^{(j)}_{ji}/s^{(j)}_{jk} = O(1) \) such that the right hand side of (10.29) as well as \( |\vartheta_i - \vartheta_k| \) is \( O(\varepsilon) \). Therefore, we must have \( y^{(j)}_i y^{(j)}_k = O(1) \). So, these two vectors are almost parallel.

10.6 Partial reorthogonalization

In Section 10.4 we have learned that the Lanczos algorithm does not yield orthogonal Lanczos vectors as it should in theory due to floating point arithmetic. In the previous section we learned that the loss of orthogonality happens as soon as Ritz vectors have converged accurately enough to eigenvectors. In this section we review an approach how to counteract the loss of orthogonality without executing full reorthogonalization [8, 9].

In [7] it is shown that if the Lanczos basis is semiorthogonal, i.e., if

\[
W_j = Q^*_j Q_j = I_j + E, \quad \|E\| < \sqrt{\varepsilon_M},
\]

then the tridiagonal matrix \( T_j \) is the projection of \( A \) onto the subspace \( \mathcal{R}(V_j) \),

\[
T_j = N_j^* A N_j + G, \quad \|G\| = O((\varepsilon_M)\|A\|),
\]

where \( N_j \) is an orthonormal basis of \( \mathcal{R}(Q_j) \). Therefore, it suffices to have semiorthogonal Lanczos vectors for computing accurate eigenvalues. Our goal is now to enforce semiorthogonality by monitoring the loss of orthogonality and to reorthogonalize if needed.

The computed Lanczos vectors satisfy

\[
(10.30) \quad \beta_j q_{j+1} = A q_j - \alpha_j q_j - \beta_{j-1} q_{j-1} + f_j,
\]

where \( f_j \) accounts for the roundoff errors committed in the \( j \)-th iteration step. Let \( W_j = ((\omega_{ik}))_{1 \leq i,k \leq j} \). Premultiplying equation (10.30) by \( q^*_k \) gives

\[
(10.31) \quad \beta_j \omega_{j+1,k} = q^*_k A q_j - \alpha_j \omega_{j,k} - \beta_{j-1} \omega_{j-1,k} + q^*_k f_j.
\]
Exchanging indices $j$ and $k$ in the last equation (10.31) gives

$$
\beta_k \omega_{j,k+1} = q_j^* A q_k - \alpha_k \omega_{j,k} - \beta_{k-1} \omega_{j,k-1} + q_j^* f_k.
$$

By subtracting (10.32) from (10.31) we get

$$
\beta_j \omega_{j+1,k} = \beta_j \omega_{j,k+1} + (\alpha_k - \alpha_j) \omega_{j,k} - \beta_{k-1} \omega_{j,k-1} - \beta_j - \omega_{j-1,k} - q_j^* f_k + q_k^* f_j.
$$

Given $W_j$ we employ equation (10.33) to compute the $j+1$-th row of $W_{j+1}$. However, elements $\omega_{j+1,j}$ and $\omega_{j+1,j+1}$ are not defined by (10.33). We can assign values to these two matrix entries by reasoning as follows.

- We set $\omega_{j+1,j+1} = 1$ because we explicitly normalize $q_{j+1}$.
- We set $\omega_{j+1,j} = O(\varepsilon_M)$ because we explicitly orthogonalize $q_{j+1}$ and $q_j$.

For computational purposes, equation (10.33) is now replaced by

$$
\omega_{j+1,k} = (\tilde{\omega} + \text{sign}(\tilde{\omega}) \frac{2\varepsilon \|A\|}{\beta_j}) / \beta_j.
$$

As soon as $\omega_{j+1,k} > \sqrt{\varepsilon_M}$ the vectors $q_j$ and $q_{j+1}$ are orthogonalized against all previous Lanczos vectors $q_1, \ldots, q_{j-1}$. Then the elements of last two lines of $W_j$ are set equal to a number of size $O(\varepsilon_M)$. Notice that only the last two rows of $W_j$ have to be stored.

**Numerical example**

We perform the Lanczos algorithm with matrix

$$A = \text{diag}(1, 2, \ldots, 50)$$

and initial vector

$$x = [1, \ldots, 1]^*.$$

In the first experiment we execute 50 iteration steps. In Table 10.1 the base-10 logarithms of the values $|w_{i,j}|$/macheps are listed where $|w_{i,j}| = |q_i^* q_j|$, $1 \leq j \leq i \leq 50$ and macheps $\approx 2.2 \cdot 10^{-16}$. One sees how the $|w_{i,j}|$ steadily grow with increasing $i$ and with increasing $|i-j|$.

In the second experiment we execute 50 iteration steps with partial reorthogonalization turned on. The estimators $\omega_{j,k}$ are computed according to (10.33),

$$
\begin{align*}
\omega_{k,k} &= 1, \quad k = 1, \ldots, j \\
\omega_{k,k-1} &= \psi_k, \quad k = 2, \ldots, j \\
\omega_{j+1,k} &= \frac{1}{\beta_j} \left[ \beta_k \omega_{j,k+1} + (\alpha_k - \alpha_j) \omega_{j,k} - \beta_{k-1} \omega_{j,k-1} - \beta_j - \omega_{j-1,k} \right] + \vartheta_{i,k}, \quad 1 \leq k \leq j.
\end{align*}
$$

Here, we set $\omega_{j,0} = 0$. The values $\psi_k$ and $\vartheta_{i,k}$ could be defined to be random variables of the correct magnitude, i.e., $O(\varepsilon k)$. Following a suggestion of Parlett [7] we used

$$
\psi_k = \varepsilon \|A\|, \quad \vartheta_{i,k} = \varepsilon \sqrt{\|A\|}.
$$
10.6. PARTIAL REORTHOGONALIZATION

Table 10.1: MATLAB demo on the loss of orthogonality among Lanczos vectors. Unmodified Lanczos. \[ \text{round} \left( \log_{10}(\text{abs}(\mathbf{I} - \mathbf{Q}^\top \mathbf{Q}/50)/\text{eps}) \right) \]
Reorthogonalization takes place in the $j$-th Lanczos step if $\max_k(\omega_{j+1,k}) > \sqrt{\text{macheps}}$. $q_{j+1}$ is orthogonalized against all vectors $q_k$ with $\omega_{j+1,k} > \text{macheps}^{3/4}$. In the following iteration step also $q_{j+2}$ is orthogonalized against these vectors. In Table 10.2 the base-10 logarithms of the values $|w_{i,j}|/$macheps obtained with this procedure are listed where $|w_{i,j}| = |q_i^*q_j|$, $1 \leq j \leq i \leq 50$ and macheps $\approx 2.2 \cdot 10^{-16}$. In Table 10.3 the base-10 logarithms of the estimates $|\omega_{i,j}|/$macheps are given. The estimates are too high by (only) an order of magnitude. However, the procedure succeeds in that the resulting $\{q_k\}$ are semi-orthogonal.

### 10.7 Block Lanczos

As we have seen, the Lanczos algorithm produces a sequence $\{q_i\}$ of orthonormal vectors. These Lanczos vectors build an orthonormal basis for the Krylov subspace $\mathcal{K}^j(x) = \text{span}\{q_1, \ldots, q_j\} \subset \mathbb{R}^n$. The restriction of $A$ to $\mathcal{K}^j(x)$ is an unreduced tridiagonal matrix. However the Lanczos algorithm cannot detect the multiplicity of the eigenvalues it computes. This limitation prompted the development of the block version of the Lanczos process (Block Lanczos algorithm), which is capable of determining multiplicities of eigenvalues up to the block size.

The idea is not to start with a single vector $q_1 \in \mathbb{R}^n$ but with a set of mutually orthogonal vectors which we take as the columns of the matrix $Q_1 \in \mathbb{R}^{n \times p}$ with the block size $p > 1$.

Associated with $Q_1$ is the 'big' Krylov subspace

$$\mathcal{K}^{jp}(Q_1) = \text{span}\{Q_1, AQ_1, \ldots, A^{j-1}Q_1\}.$$  

(We suppose, for simplicity, that $A^{-1}Q_1$ has rank $p$. Otherwise we would have to consider variable block sizes.)

The approach is similar to the scalar case with $p = 1$: Let $Q_1, \ldots, Q_j \in \mathbb{R}^{n \times p}$ be pairwise orthogonal block matrices ($Q_i^*Q_k = 0$ for $i \neq k$) with orthonormal columns ($Q_i^*Q_i = I_p$ for all $i \leq j$). Then, in the $j$-th iteration step, we obtain the matrix $AQ_j$ and orthogonalize it against matrices $Q_i$, $i \leq j$. The columns of the matrices are obtained by means of the QR factorization or with the Gram–Schmidt orthonormalization process. We obtained the following:

**Algorithm 10.5 Block Lanczos algorithm**

1. Choose $Q_1 \in \mathbb{R}^{n \times p}$ such that $Q_1^*Q_1 = I_p$. Set $j := 0$ and $\mathbb{R}^{n \times p} \ni V := 0$.

   This algorithm generates a block tridiagonal matrix $T_j$ with the diagonal blocks $A_i$, $i \leq j$, the lower diagonal blocks $B_i$, $i < j$, and the Krylov basis $\{Q_1, \ldots, Q_j\}$ of $\mathcal{K}^{jp}(Q_1)$.

2. for $j \geq 0$ do
3.   if $j > 0$ then
4.     $V := Q_{j+1}B_j$; /* QR decomposition */
5.     $V := -Q_jB_j^*$;
6.   end if
7.   $j := j + 1$;
8.   $A_j := Q_j^*V$;
9.   $V := V - Q_jA_j$;
10. Test for convergence (Ritz pairs, evaluation of error)
11. end for
Table 10.2: MATLAB demo on the loss of orthogonality among Lanczos vectors: Lanczos with partial reorthogonalization. 
\[
\text{round}(\log_{10}(\text{abs}(I-Q_{50}Q_{50})/\text{eps}))
\]
Table 10.3: MATLAB demo on the loss of orthogonality among Lanczos vectors: Lanczos with partial reorthogonalization.

\[ \text{round}(\log_{10}(\text{abs}(I-\hat{W}_{50})/\text{eps})) \]
Let $\hat{Q}_j := [Q_1, Q_2, \ldots, Q_j]$ be the Krylov basis generated by Algorithm 10.5. Then, in this basis, the projection of $A$ is the block tridiagonal matrix $\hat{T}_j$

$$\hat{Q}_j^* A \hat{Q}_j = \hat{T}_j = \begin{pmatrix} A_1 & B_1^* & & \\ B_1 & A_2 & \ddots & \\ & \ddots & \ddots & B_{j-1}^* \\ & & B_{j-1} & A_j \end{pmatrix}, \quad A_i, B_i \in \mathbb{R}^{p \times p}.$$ 

If matrices $B_i$ are chosen to be upper triangular, then $\hat{T}_j$ is a band matrix with bandwidth $2p + 1$!

Similarly as in scalar case, in the $j$-th iteration step we obtain the equation

$$A \hat{Q}_j - \hat{Q}_j \hat{T}_j = Q_{j+1} B_j E_j^* + \hat{F}_j, \quad E_j = \begin{pmatrix} O \\ \vdots \\ O \\ I_p \end{pmatrix},$$

where $\hat{F}_j$ accounts for the effect of roundoff error. Let $(\vartheta_i, y_i)$ be a Ritz pair of $A$ in $K_{jp}(Q_1)$. Then

$$y_i = \hat{Q}_j s_i, \quad \hat{T}_j s_i = \vartheta_i s_i.$$ 

As before, we can consider the residual norm to study the accuracy of the Ritz pair $(\vartheta_i, y_i)$ of $A$

$$\|Ay_i - \vartheta_i y_i\| = \|A\hat{Q}_j s_i - \vartheta_i \hat{Q}_j s_i\| \approx \|Q_{j+1} B_j E_j^* s_i\| = \left\| B_j \begin{pmatrix} s_{j(p-1)+1,i} \\ \vdots \\ s_{jp+1,i} \end{pmatrix} \right\|.$$ 

We have to compute the bottom $p$ components of the eigenvectors $s_i$ in order to test for convergence.

Similarly as in the scalar case, the mutual orthogonality of the Lanczos vectors (i.e., the columns of $\hat{Q}_j$) is lost, as soon as convergence sets in. The remedies described earlier are available: full reorthogonalization or selective orthogonalization.

### 10.8 External selective reorthogonalization

If many eigenvalues are to be computed with the Lanczos algorithm, it is usually advisable to execute shift-and-invert Lanczos with varying shifts [4].

In each new start of a Lanczos procedure, one has to prevent the algorithm from finding already computed eigenpairs. We have encountered this problem when we tried to compute multiple eigenpairs by simple vector iteration. Here, the remedy is the same as there. In the second and further runs of the Lanczos algorithm, the starting vectors are made orthogonal to the already computed eigenvectors. We know that in theory all Lanczos vectors will be orthogonal to the previously computed eigenvectors. However, because the previous eigenvectors have been computed only approximately the initial vectors are not orthogonal to the true eigenvectors. Because of this and because of floating point errors loss of orthogonality is observed. The loss of orthogonality can be monitored similarly as with partial reorthogonalization. For details see [4].
Bibliography

Chapter 11

Restarting Arnoldi and Lanczos algorithms

The number of iteration steps can be very high with the Arnoldi or the Lanczos algorithm. This number is, of course, not predictable. The iteration count depends on properties of the matrix, in particular the distribution of its eigenvalues, but also on the initial vectors.

High iteration counts entail a large memory requirement to store the Arnoldi/Lanczos vectors and a high amount of computation because of growing cost of the reorthogonalization.

The idea behind the implicitly restarted Arnoldi (IRA) and implicitly restarted Lanczos (IRL) algorithms is to reduce these costs by limiting the dimension of the search space. This means that the iteration is stopped after a number of steps (which is bigger than the number of desired eigenvalues), reduce the dimension of the search space without destroying the Krylov space structure, and finally resume the Arnoldi / Lanczos iteration.

The implicitly restarted Arnoldi has first been proposed by Sorensen [7, 8]. It is implemented together with the implicitly restarted Lanczos algorithms in the software package ARPACK [4]. The ARPACK routines are the basis for the sparse matrix eigensolver `eigs` in MATLAB.

11.1 The $m$-step Arnoldi iteration

Algorithm 11.1 The $m$-step Arnoldi iteration

1: Let $A \in \mathbb{F}^{n \times n}$. This algorithm executes $m$ steps of the Arnoldi algorithm.
2: $q_1 = x/\|x\|$; \quad $z = Aq_1$; \quad $\alpha_1 = q_1^*z$;
3: $r_1 = w - \alpha_1 q_1$; \quad $Q_1 = [q_1]$; \quad $H_1 = [\alpha_1]$;
4: for $j = 1, \ldots, m - 1$ do
5: \quad $\beta_j := \|r_j\|$; \quad $q_{j+1} = r_j/\beta_j$;
6: \quad $Q_{j+1} := [Q_j, q_{j+1}]$; \quad $H_j := \begin{bmatrix} H_j \\
\beta_j e_j^T \end{bmatrix} \in \mathbb{F}^{(j+1) \times j}$;
7: \quad $z := Aq_j$;
8: \quad $h := Q_{j+1}^*z$; \quad $r_{j+1} := z - Q_{j+1}h$;
9: \quad $H_{j+1} := [H_j, h]$;
10: end for

We start with the Algorithm 11.1 that is a variant of the Arnoldi Algorithm 10.1. It
CHAPTER 11. RESTARTING ARNOLDI AND LANCZOS ALGORITHMS

executes just $m$ Arnoldi iteration steps. We will now show how the dimension of the search space is reduced without losing the information regarding the eigenvectors one is looking for.

Remark 11.1. Step 8 in Algorithm 11.1 is classical Gram–Schmidt orthogonalization. As $r_{j+1} = z - Q_{j+1} h = z - Q_{j+1} Q^*_{j+1} z$,

we formally have $Q^*_{j+1} r_{j+1} = 0$. However, classical Gram–Schmidt orthogonalization is faster but not so accurate as modified Gram–Schmidt orthogonalization [1]. So, often, $Q^*_{j+1} r_{j+1}$ is quite large. Therefore, the orthogonalization is iterated to get sufficient orthogonality.

A possible modification of step 8 that incorporates a second iteration is

8: \[ h := Q^*_{j+1} z; \quad r_{j+1} := z - Q_{j+1} h; \]
\[ c := Q^*_{j+1} r_{j+1}; \quad r_{j+1} := r_{j+1} - Q_{j+1} c; \quad h = h + c; \]

Now we have,

\[ \tilde{r}_{j+1} = \text{corrected } r_{j+1} \]
\[ = r_{j+1} - Q_{j+1} Q^*_{j+1} r_{j+1} \]
\[ = z - Q_{j+1} Q^*_{j+1} z - Q_{j+1} Q^*_{j+1} r_{j+1} = z - Q_{j+1} (h + c) \]

More iterations are possible but seldom necessary.

After the execution of Algorithm 11.1 we have the Arnoldi / Lanczos relation

\[ AQ_m = Q_m H_m + r_m e^*_m, \quad H_m = [ \begin{array}{c} \vdots \\ \end{array} ] \]

available with

\[ r_m = \beta_m q_{m+1}, \quad \|q_{m+1}\| = 1. \]

If $\beta_m = 0$ then $\mathcal{R}(Q_m)$ is invariant under $A$, i.e., $Ax \in \mathcal{R}(Q_m)$ for all $x \in \mathcal{R}(Q_m)$. This lucky situation implies that $\sigma(H_m) \subset \sigma_m(A)$. So, the Ritz values and vectors are eigenvalues and eigenvectors of $A$.

What we can realistically hope for is $\beta_m$ being small. Then,

\[ AQ_m - r_m e^*_m = (A - r_m q^*_m) Q_m = Q_m H_m. \]

Then, $\mathcal{R}(Q_m)$ is invariant under a matrix $A + E$, that differs from $A$ by a perturbation $E$ with $\|E\| = \|r_m\| = |\beta_m|$. From general eigenvalue theory we know that in this situation well-conditioned eigenvalues of $H_m$ are good approximations of eigenvalues of $A$.

In the sequel we investigate how we can find a $q_1$ such that $\beta_m$ becomes small?

11.2 Implicit restart

Let us start from the Arnoldi relation

\[ AQ_m = Q_m H_m + r_m e^*_m, \]

available with
11.2. IMPLICIT RESTART

Algorithm 11.2 $k$ implicit QR steps applied to $H_m$

1: $H_m^+ := H_m$.
2: for $i := 1, \ldots, k$ do
3: $H_m^+ := V_i^* H_m^+ V_i$, where $H_m^+ - \mu_i I = V_i R_i$ (QR factorization)
4: end for

that is obtained after calling Algorithm 11.1.

We apply $k < m$ implicit QR steps to $H_m$ with shifts $\mu_1, \ldots, \mu_k$, see Algorithm 11.2. Let $V^+ := V_1 V_2 \cdots V_k$. $V^+$ is the product of $k$ (unitary) Hessenberg matrices whence it has $k$ nonzero off-diagonals below its main diagonal.

$$V_m^+ = \begin{bmatrix} \vdots & \vdots \end{bmatrix}$$

We define $Q_m^+ := Q_m V^+$, $H_m^+ := (V^+)^* H_m V^+$.

Then, from (11.2) we obtain

$$AQ_m V^+ = Q_m V^+ (V^+)^* H_m V^+ + r_m e_m^* V^+,$$

or

(11.3) $$AQ_m^+ = Q_m^+ H_m^+ + r_m e_m^* V^+.$$  

As $V^+$ has $k$ nonzero off-diagonals below the main diagonal, the last row of $V^+$ has the form

$$e_m^* V^+ = (0, \ldots, 0, *, \ldots,*), \quad k + p = m.$$  

We now simply discard the last $k$ columns of (11.3).

$$AQ_m^+(:,1:p) = Q_m^+ H_m^+(:,1:p) + r_m e_m^* V^+(:,1:p)$$

$$= Q_m^+(:,1:p) H_m^+(1:p,1:p) + \begin{bmatrix} h_{p+1}^+ & q_{p+1}^+ e_p & e_m^* \beta_p \end{bmatrix}$$

$$= Q_m^+(:,1:p) H_m^+(1:p,1:p) + \begin{bmatrix} q_{p+1}^+ h_{p+1}^+ & r_m e_m^* \end{bmatrix} e_p^*.$$

In Algorithm 11.3 we have collected what we have derived so far. We have however left open in step 3 of the algorithm how the shifts $\mu_1, \ldots, \mu_k$ should be chosen. In ARPACK [4], all eigenvalues of $H_m$ are computed. Those $k$ eigenvalues that are furthest away from some target value are chosen as shifts. We have not specified how we determine convergence, too.

One can show that a QR step with shift $\mu_i$ transforms the vector $q_1$ in a multiple of $(A - \mu_i I) q_1$. In fact, a simple modification of the Arnoldi relation (11.2) gives

$$(A - \mu_i I) Q_m = Q_m (H_m - \mu_i I) + r_m e_m^* = Q_m V_1 R_1 + r_m e_m^*.$$  

$V_1 R_1$
Algorithm 11.3 Implicitly restarted Arnoldi (IRA)

1: Let the Arnoldi relation $AQ_m = Q_m H_m + r_m e^*_m$ be given.
2: repeat
3: Determine $k$ shifts $\mu_1, \ldots, \mu_k$;
4: $v^* := e^*_m$;
5: for $i = 1, \ldots, k$ do
6: $H_m - \mu_i I = V_i R_i$; /* QR factorization */
7: $H_m := V^*_i H_m V_i$; $Q_m := Q_m V_i$;
8: $v^* := v^* V_i$;
9: end for
10: $r_p := q^{(1)}_1^T \beta_1 + r_m v^*_m$;
11: $Q_p := Q_m(:, 1 : p)$; $H_p := H_m(1 : p, 1 : p)$;
12: Starting with $AQ_p = Q_p H_p + r_p e^*_p$
execute $k$ additional steps of the Arnoldi algorithm until
$AQ_m = Q_m H_m + r_m e^*_m$.
13: until convergence

Comparing the first columns in this equation gives

$$(A - \mu_i I)q_1 = Q_m V_1 e_{111} + 0 = q^{(1)}_1^T r_{11}. \tag{11.4}$$

By consequence, all $k$ steps combined give

$$q_1 \leftarrow \Psi(A)q_1, \quad \Psi(\lambda) = \prod_{i=1}^k (\lambda - \mu_i).$$

If $\mu_i$ were an eigenvalue of $A$ then $(A - \mu_i I)q_1$ removes components of $q_1$ in the direction of the corresponding eigenvector. More general, if $\mu_i$ is close to an eigenvalue of $A$ then $(A - \mu_i I)q_1$ will have only small components in the direction of eigenvectors corresponding to nearby eigenvalues. Choosing the $\mu_i$ equal to Ritz values far away from the desired part of the spectrum thus enhances the desired component. Still there is the danger that in each sweep on Algorithm 11.3 the same undesired Ritz values are recovered. Therefore, other strategies for choosing the shifts have been proposed [2]. Experimental results indicate however, that the original strategy chosen in ARPACK mostly works best.

11.3 Convergence criterion

Let $H_m s = s \vartheta$ with $\|s\| = 1$. Let $\hat{x} = Q_m s$. Then we have as earlier

$$(11.4) \quad \|A\hat{x} - \vartheta \hat{x}\| = \|AQ_m s - Q_m H_m s\| = \|r_m\| |e^*_m s| = \beta_m |e^*_m s|.$$  

In the Hermitian case, $A = A^*$, the Theorem 10.1 of Krylov–Bogoliubov provides an interval that contains an eigenvalue of $A$. In the general case, we have

$$(11.5) \quad (A + E) \hat{x} = \vartheta \hat{x}, \quad E = -r_m q_m, \quad \|E\| = \|r_m\| = \beta_m.$$
According to an earlier theorem we know that if $\lambda \in \sigma(A)$ is simple and $\vartheta$ is the eigenvalue of $A + E$ closest to $\lambda$, then
\begin{equation}
|\lambda - \vartheta| \leq \frac{||E||}{y^*x} + O(||E||^2).
\end{equation}

Here, $y$ and $x$ are left and right eigenvectors of $E$ corresponding to the eigenvalue $\lambda$. A similar statement holds for the eigenvectors, but the distance (gap) to the next eigenvalue comes into play as well.

In ARPACK, a Ritz pair $(\vartheta, \tilde{x})$ is considered converged if
\begin{equation}
\beta_m|e_m^*s| \leq \max(\varepsilon_M H_m \|, \text{tol} \cdot |\vartheta|).
\end{equation}

As $|\vartheta| \leq \|H_m\| \leq \|A\|$, the inequality $||E|| \leq \text{tol} \cdot \|A\|$ holds at convergence. According to (11.6) well-conditioned eigenvalues are well approximated.

### 11.4 The generalized eigenvalue problem

Let us consider now the generalized eigenvalue problem
\begin{equation}
Ax = \lambda Mx.
\end{equation}

Applying a shift-and-invert spectral transformation with shift $\sigma$ transforms (11.8) into
\begin{equation}
Sx = (A - \sigma M)^{-1}Mx = \mu x, \quad \mu = \frac{1}{\lambda - \sigma}.
\end{equation}

We now execute an Arnoldi/Lanczos iteration with $S$ to obtain
\begin{equation}
SQ_m = Q_mH_m + r_m e_m^*, \quad Q_m^*M Q_m = I_m, \quad Q_m^* M r_m = 0.
\end{equation}

Let $s$ with $\|s\| = 1$ be an eigenvector of $H_m$ with Ritz value $\vartheta$. Let $y = Q_m s$ be the associated Ritz vector. Then,
\begin{equation}
SQ_m s = Sy = Q_m H_m s + r_m e_m^* s = y \vartheta + r_m e_m^* s.
\end{equation}

So, $y \vartheta + r_m e_m^* s$ can be considered a vector that is obtained by one step of inverse iteration. This vector is an improved approximation to the desired eigenvector, obtained at negligible cost. This so-called eigenvector purification is particularly important if $M$ is singular.

Let us bound the residual norm of the purified vector. With (11.11) we have
\begin{equation}
M y = (A - \sigma M)(y \vartheta + r_m e_m^* s)
\end{equation}

with

\[||\tilde{y}|| = \sqrt{\vartheta^2 + \beta_k^2|e_m^* s|^2}.\]

This equality holds as $y \perp M r$. By consequence,
\begin{equation}
\|A \tilde{y} - \lambda M \tilde{y}\| = \|(A - \sigma M) \tilde{y} + M \tilde{y} (\sigma - \lambda)\|
\end{equation}

\[= \|M y - M (y \vartheta + r_m e_m^* s) / \vartheta\| = \|M r\| \| e_m^* s \| / |\vartheta|.
\]

Since $|\vartheta|$ is large in general, we obtain good bounds for the residual of the purified eigenvectors.
CHAPTER 11. RESTARTING ARNOLDI AND LANCZOS ALGORITHMS

EIGS Find a few eigenvalues and eigenvectors of a matrix using ARPACK

\[ \text{D = EIGS}(\text{A}) \text{ returns a vector of } \text{A's 6 largest magnitude eigenvalues.} \]
\[ \text{A must be square and should be large and sparse.} \]

\[ [\text{V}, \text{D}] = \text{EIGS}(\text{A}) \text{ returns a diagonal matrix } \text{D of } \text{A's 6 largest magnitude eigenvalues and a matrix } \text{V whose columns are the corresponding eigenvectors.} \]

\[ [\text{V}, \text{D}, \text{FLAG}] = \text{EIGS}(\text{A}) \text{ also returns a convergence flag. If } \text{FLAG is 0 then all the eigenvalues converged; otherwise not all converged.} \]

EIGS(A,B) solves the generalized eigenvalue problem A*V == B*V*D. B must be symmetric (or Hermitian) positive definite and the same size as A. EIGS(A,[],...) indicates the standard eigenvalue problem A*V == V*D.

EIGS(A,K) and EIGS(A,B,K) return the K largest magnitude eigenvalues.

EIGS(A,K,SIGMA) and EIGS(A,B,K,SIGMA) return K eigenvalues. If SIGMA is:

- 'LM' or 'SM' - Largest or Smallest Magnitude
- 'LA' or 'SA' - Largest or Smallest Algebraic
- 'BE' - Both Ends, one more from high end if K is odd

For nonsymmetric and complex problems, SIGMA may also be:

- 'LR' or 'SR' - Largest or Smallest Real part
- 'LI' or 'SI' - Largest or Smallest Imaginary part

If SIGMA is a real or complex scalar including 0, EIGS finds the eigenvalues closest to SIGMA. For scalar SIGMA, and when SIGMA = 'SM', B need only be symmetric (or Hermitian) positive semi-definite since it is not Cholesky factored as in the other cases.

EIGS(A,K,SIGMA,OPTS) and EIGS(A,B,K,SIGMA,OPTS) specify options:

OPTS.issym: symmetry of A or A-SIGMA*B represented by AFUN [false | true]
OPTS.isreal: complexity of A or A-SIGMA*B represented by AFUN [false | true]
OPTS.tol: convergence: Ritz estimate residual <= tol*NORM(A) [scalar | eps]
OPTS.maxit: maximum number of iterations [integer | 300]
OPTS.p: number of Lanczos vectors: K+1<p<=N [integer | 2K]
OPTS.v0: starting vector [N-by-1 vector | randomly generated]
OPTS.disp: diagnostic information display level [0 | 1 | 2]
OPTS.cholB: B is actually its Cholesky factor CHOL(B) [false | true]
OPTS.permB: sparse B is actually CHOL(B(permB,permB)) [permB | 1:N]

Use CHOL(B) instead of B when SIGMA is a string other than 'SM'.

EIGS(AFUN,N) accepts the function AFUN instead of the matrix A. AFUN is a function handle and Y = AFUN(X) should return

A\X if SIGMA is unspecified, or a string other than 'SM'
A\X if SIGMA is 0 or 'SM'

N is the size of A. The matrix A, A-SIGMA*I or A-SIGMA*B represented by AFUN is assumed to be real and nonsymmetric unless specified otherwise by OPTS.isreal and OPTS.issym. In all these EIGS syntaxes, EIGS(A,...) may be replaced by EIGS(AFUN,N,...).

Example:

\[ A = \text{delsq(numgrid('C',15))}; \]
\[ d1 = \text{eigs}(A,5,'SM'); \]

Equivalently, if dnRk is the following one-line function:

\[
\begin{align*}
\text{function } y &= \text{dnRk}(x,R,k) \\
\text{y} &= (\text{delsq(numgrid(R,k)))) \backslash x; \\
\text{endfunction}
\end{align*}
\]

\[ n = \text{size(A,1)}; \]
\[ \text{opts.issym} = 1; \]
\[ d2 = \text{eigs}(@(x)\text{dnRk}(x, 'C', 15), n, 5, 'SM', \text{opts}); \]

See also eig, svds, ARPACKC, function_handle.
11.5 A numerical example

This example is taken from the MATLAB document pages regarding \texttt{eigs}. \texttt{eigs} is the MATLAB interface to the ARPACK code, see page 200. The matrix called \texttt{west0479} is a $479 \times 479$ matrix originating in a chemical engineering plant model. The matrix is available from the Matrix Market \cite{MatrixMarket}, a web site that provides numerous test matrices. Its nonzero structure is given in Fig. 11.1

![479x479 Matrix west0479](image)

Figure 11.1: Nonzero structure of the $479 \times 479$ matrix west0479

To compute the eight largest eigenvalues of this matrix we issue the following MATLAB commands.

```
>> load west0479
>> d = eig(full(west0479));
>> dlm=eigs(west0479,8);

The output indicates that eigs needs seven sweeps to compute the eigenvalues to the default accuracy of macheps∥A∥. The Ritz values given are the approximations of the eigenvalues we want to compute. The complete spectrum of west0479 is given in Fig. 11.2. Notice the different scales of the axes! Fig. 11.3 is a zoom that shows all eigenvalues except the two very large ones. Here the axes are equally scaled. From the two figures it becomes clear that eigs has computed the eight eigenvalues (and corresponding eigenvectors) of largest modulus.

To compute the eigenvalues smallest in modulus we issue the following command.

dsm=eigs(west0479,8,'sm');

11.7 The Lanczos algorithm with thick restarts

The implicit restarting procedures discussed so far are very clever ways to get rid of unwanted directions in the search space and still keeping a Lanczos or Arnoldi basis. The latter admits to continue the iteration in a known framework. The Lanczos or Arnoldi relations hold that admit very efficient checks for convergence. The restart has the effect of altering the starting vector.

In this and the next section we discuss algorithms that work with Krylov spaces but are not restricted to Krylov or Arnoldi bases. Before continuing we make a step back and consider how we can determine if a given subspace of \( \mathbb{F}^n \) is a Krylov space at all.

Let \( A \) be an \( n \times n \) matrix and let \( v_1, \ldots, v_k \) be linearly independent \( n \)-vectors. Is the subspace \( \mathcal{V} := \text{span}\{v_1, \ldots, v_k\} \) a Krylov space, i.e., is there a vector \( q \in \mathcal{V} \) such that \( \mathcal{V} = \mathcal{K}_k(A, q) \)? The following theorem gives the answer [3, 10].

**Theorem 11.1** \( \mathcal{V} = \text{span}\{v_1, \ldots, v_k\} \) is a Krylov space if and only if there is a \( k \times k \) matrix \( M \) such that

\[
R := AV - VM, \quad V = [v_1, \ldots, v_k],
\]

has rank one and \( \text{span}\{v_1, \ldots, v_k, \mathcal{R}(R)\} \) has dimension \( k + 1 \).
11.7. THE LANCZOS ALGORITHM WITH THICK RESTARTS

Proof. Let us first assume that \( V = K_k(A, q) \) for some \( q \in \mathcal{V} \). Let \( Q = [q_1, \ldots, q_k] \) be the Arnoldi basis of \( K_k(A, q) \). Then \( Q = VS \) with \( S \) a nonsingular \( k \)-by-\( k \) matrix. We now multiply the Arnoldi relation

\[
AQ = QH + \tilde{q}_{k+1}e_k^T, \quad Q^*\tilde{q}_{k+1} = 0, \quad H \text{ Hessenberg.}
\]

by \( S^{-1} \) from the right to get

\[
AV = VSHS^{-1} + \tilde{q}_{k+1}e_k^TS^{-1}.
\]

which is (11.15) with \( M = SHS^{-1} \).

Let us now assume that \( R \) in (11.15) has rank 1 so that we can write

\[
(11.16) \quad AV = VM + R = VM + \mathbf{v}\mathbf{w}^*, \quad M \in \mathbb{F}^{k \times k}.
\]

with some \( \mathbf{v} \in \mathbb{F}^n \) and \( \mathbf{w} \in \mathbb{F}^k \). Let \( S_1, S_1^{-1} = S_1^* \), be the Householder reflector that maps \( \mathbf{w} \) onto a multiple of \( e_k \), \( S_1^*\mathbf{w} = \gamma e_k \). Then, (11.16) becomes

\[
AVS_1 = VSS_1^{*}MS_1 + \gamma \mathbf{v}\mathbf{e}_k^T.
\]

There is another unitary matrix \( S_2 \) with \( S_2^*e_k = e_k \) that transforms \( S_1^{*}MS_1 \) similarly to Hessenberg form,

\[
S^*MS = H, \quad H \text{ Hessenberg,}
\]

where \( S = S_1S_2 \). \( S_2 \) can be formed as the product of Householder reflectors. In contrast to the well-known transformation of full matrices to Hessenberg form, here the zeros are generated row-wise starting with the last in order not to destroy \( e_k \) in the rank-1 term. Thus,

\[
AVS = VSH + \gamma \mathbf{v}\mathbf{e}_k^T.
\]

So, \( \mathcal{V} = K_k(A, q) \) with \( q = VS\mathbf{e}_1 \).

We apply this theorem to the case where a subspace is spanned by some Ritz vectors. Let \( A = A^* \) and let

\[
(11.17) \quad AQ_k - Q_kT_k = \beta_{k+1}q_{k+1}e_k^T
\]

be a Lanczos relation. Let

\[
T_kS_k = S_k\Theta_k, \quad S_k = [s_1^{(k)}, \ldots, s_k^{(k)}], \quad \Theta_k = \text{diag}(\theta_1, \ldots, \theta_k).
\]

be the spectral decomposition of the tridiagonal matrix \( T_k \). Then, for all \( i \), the Ritz vector \( y_i = Q_k s_i^{(k)} \in K_k(A, q) \)

gives rise to the residual

\[
r_i = Ay_i - y_i\theta_i = \beta_{k+1}q_{k+1}e_k^Ts_i^{(k)} \in K_{k+1}(A, q) \oplus K_k(A, q).
\]

Therefore, for any set of indices \( 1 \leq i_1 < \cdots < i_j \leq k \) we have

\[
A[y_{i_1}, y_{i_2}, \ldots, y_{i_j}] - [y_{i_1}, y_{i_2}, \ldots, y_{i_j}] \text{diag}(\theta_{i_1}, \ldots, \theta_{i_j}) = \beta_{k+1}q_{k+1}[s_{i_1}^{(k)}, s_{i_2}^{(k)}, \ldots, s_{i_j}^{(k)}].
\]

By Theorem 11.1 we see that any set \([y_{i_1}, y_{i_2}, \ldots, y_{i_j}] \) of Ritz vectors forms a Krylov space. Note that the generating vector differs for each set.
Algorithm 11.4 Thick restart Lanczos

1. Let us be given \( k \) Ritz vectors \( y_i \) and a residual vector \( r_k \) such that \( Ay_i = \vartheta_i y_i + \sigma_i r_k \), \( i = 1, \ldots, k \). The value \( k \) may be zero in which case \( r_0 \) is the initial guess.

This algorithm computes an orthonormal basis \( y_1, \ldots, y_j, q_{j+1}, \ldots, q_m \) that spans a \( m \)-dimensional Krylov space whose generating vector is not known unless \( k = 0 \).

2. \( q_{k+1} := r_k / \|r_k\| \).
3. \( z := Az_{k+1} \).
4. \( \alpha_{k+1} := q_{k+1}^* z \).
5. \( r_{k+1} = z - \alpha_{k+1}q_{k+1} - \sum_{i=1}^{k} \sigma_i y_i \).
6. \( \beta_{k+1} := \|r_{k+1}\| \).
7. \( \text{for } i = k + 2, \ldots, m \) do
8. \( q_i := r_{i-1} / \beta_{i-1} \).
9. \( z := Az_i \).
10. \( \alpha_i := q_i^* z \).
11. \( r_i = z - \alpha_i q_i - \beta_{i-1} q_{i-1} \).
12. \( \beta_i = \|r_i\| \).
13. \( \text{end for} \)

We now split the indices \( 1, \ldots, k \) in two sets. The first set contains the ‘good’ Ritz vectors that we want to keep and that we collect in \( Y_1 \), the second set contains the ‘bad’ ones that we want to remove. Those we put in \( Y_2 \). In this way we get

\[
A[Y_1, Y_2] - [Y_1, Y_2] \begin{bmatrix} \Theta_1 \\ \Theta_2 \end{bmatrix} = \beta_{k+1} q_{k+1} [s_1^*, s_2^*].
\]

Keeping the first set of Ritz vectors and purging (deflating) the rest yields

\[
AY_1 - Y_1 \Theta_1 = \beta_{k+1} q_{k+1} s_1^*.
\]

We now can restart a Lanczos procedure by orthogonalizing \( Aq_{k+1} \) against \( Y_1 =: [y_1^*, \ldots, y_j^*] \) and \( q_{k+1} \). From the equation

\[
Ay_i - y_i \vartheta_i = q_{k+1} \sigma_i, \quad \sigma_i = \beta_{k+1} e_{k+1}^* s_i^{(k)}
\]

we get

\[
q_{k+1}^* Ay_{\ell} = \sigma_\ell,
\]

whence

\[
r_{k+1} = Aq_{k+1} - \alpha_{k+1}q_{k+1} - \sum_{i=1}^{j} \sigma_i y_i \perp K_{k+1}(A, q_{k+1}).
\]

From this point on the Lanczos algorithm proceeds with the ordinary three-term recurrence. We finally arrive at a relation similar to (11.17), however, with

\[
Q_m = [y_1, \ldots, y_j, q_{k+1}, \ldots, q_{m+k-j}]
\]

and

\[
T_m = \begin{pmatrix}
\vartheta_1 & \sigma_1 & & \\
& \ddots & \ddots & \\
& & \vartheta_j & \sigma_j \\
\sigma_1 & \cdots & \sigma_j & \alpha_{k+1} & \\
& & & & \ddots \\
& & & & \beta_{m+k-j-1}
\end{pmatrix}
\]
11.8. KRYLOV–SCHUR ALGORITHM

This procedure, called thick restart, has been suggested by Wu & Simon [11], see Algorithm 11.4. It allows to restart with any number of Ritz vectors. In contrast to the implicitly restarted Lanczos procedure, here we need the spectral decomposition of $T_m$. Its computation is not an essential overhead in general. The spectral decomposition admits a simple sorting of Ritz values. We could further split the first set of Ritz pairs into converged and unconverged ones, depending on the value $\beta_{m+1}|s_{k,i}|$. If this quantity is below a given threshold we set the value to zero and lock (deflate) the corresponding Ritz vector, i.e., accept it as an eigenvector.

The procedure is mathematically equivalent with the implicitly restarted Lanczos algorithm. In fact, the generating vector of the Krylov space span$\{y_1, \ldots, y_j, q_{j+1}, \ldots, q_m\}$ that we do not compute is $q'_1 = (A - \vartheta_{j+1}I) \cdots (A - \vartheta_mI)q_1$. This restarting procedure is probably simpler than with IRL.

The problem of losing orthogonality is similar to plain Lanczos. Wu & Simon [11] investigate the various reorthogonalizing strategies known from plain Lanczos (full, selective, partial). In their numerical experiments the simplest procedure, full reorthogonalization, performs similarly or even faster than the more sophisticated reorthogonalization procedures.

Remark 11.2. The thick restart Lanczos procedure does not need a Krylov basis of span$\{y_1, \ldots, y_j\}$ or, equivalently, the tridiagonalization of

$$
\begin{pmatrix}
\vartheta_1 & \sigma_1 \\
\sigma_1 & \ddots & \ddots \\
\vdots & \ddots & \ddots & \sigma_j \\
\vartheta_j & \sigma_j & \cdots & \sigma_j & \alpha_{k+1}
\end{pmatrix}
$$

However, at the next restart, the computation of the spectral decomposition will most probably require it.

Question: How can the arrow matrix above be tridiagonalized economically? □

11.8 Krylov–Schur algorithm

The Krylov–Schur algorithm introduced by Stewart [9] is a generalization of the thick-restart procedure for non-Hermitian problems. The Arnoldi algorithm constructs the Arnoldi relation

\begin{equation}
AQ_m = Q_m H_m + r_m e_m^*,
\end{equation}

where $H_m$ is Hessenberg and $[Q_m, r_m]$ has full rank. Let $H_m = S_m T_m S_m^*$ be a Schur decomposition of $H_m$ with unitary $S_m$ and triangular $T_m$. Then, similarly as in the previous section we have

\begin{equation}
AY_m = Y_m T_m + r_m s^*, \quad Y_m = Q_m S_m, \quad s^* = e_m^* S_m.
\end{equation}

The upper triangular form of $T_m$ eases the analysis of the individual Ritz pairs. In particular, it admits moving unwanted Ritz values to the lower-right corner of $T_m$. (See the subroutine \texttt{trexc} in LAPACK for details.) Similarly as in (11.18) we collect the ‘good’ and ‘bad’ Ritz vectors in matrices $Y_1$ and $Y_2$, respectively. In this way we get

\begin{equation}
A[Y_1, Y_2] - [Y_1, Y_2] \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} = \beta_{k+1} q_{k+1} [s_1^*, s_2^*].
\end{equation}
CHAPTER 11. RESTARTING ARNOLDI AND LANCZOS ALGORITHMS

Keeping the first set of Ritz vectors and purging the rest yields

$$AY_1 - Y_1T_{11} = \beta_{k+1}q_{k+1}s_1^*.$$  

In the thick-restart Lanczos procedure we have found an eigenpair as soon as $\beta_{k+1}|s_{ik}|$ is sufficiently small. The determination of a converged subspace with the general Krylov–Schur procedure is not so easy. However, if we manage to bring $s_1$ into the form

$$s_1 = \begin{bmatrix} s'_1 \\ s''_1 \end{bmatrix} = \begin{bmatrix} 0 \\ s''_1 \end{bmatrix},$$

then we found an invariant subspace.

In most cases $s'_1$ consists of a single small element or of two small elements in the case of a complex-conjugate eigenpair of a real nonsymmetric matrix [9]. These small elements are then declared zero and the columns in $Y'_1$ are locked, i.e., they are not altered anymore in the future computations. Orthogonality against them has to be enforced in the continuation of the eigenvalue computation though.

11.9 The rational Krylov space method

After having computed a number of eigenvalue–eigen/Schurvector pairs in the neighborhood of some shift $\sigma_1$ with the shift-invert Lanczos, Arnoldi, or Krylov–Schur algorithm it may be advisable to restart with a changed shift $\sigma_2$. This is in fact possible without discarding the available Krylov space [6]. In this section we consider the generalized eigenvalue problem $Ax = \lambda Bx$.

The rational Krylov space method starts out as a shift-invert Arnoldi iteration with shift $\sigma_1$ and starting vector $v_1$. It computes an orthonormal basis $V_j$ using the basic recurrence,

$$(A - \sigma_1 B)^{-1}BQ_j = Q_jH_j + r_je^T = Q_{j+1}\tilde{H}_j.$$  

or, using the Schur decomposition of $H_j$, cf. (11.20),

$$Y_j = Y_jT_j + r_js^* = Y_{j+1} \begin{bmatrix} T_j \\ s^* \end{bmatrix}, \quad Y_{j+1} = [Y_j, r_j]$$

We want to derive a Krylov–Schur relation for a new shift $\sigma_2 \neq \sigma_1$ from (11.23) for the same space $\mathcal{R}(Y_{j+1})$ without accessing the matrices $A$ or $B$. The tricky thing is to avoid discard all the information gathered in the basis $Y_{j+1}$ that was computed with the old shift $\sigma_1$. This is indeed possible if we replace the basis $Y_{j+1}$ with a new basis $W_{j+1}$, which spans the same subspace as $Y_{j+1}$ but can be interpreted as the orthonormal basis of a Krylov–Schur relation with the new shift $\sigma_2$.

We rewrite the relation (11.23) as

$$BY_j = BY_{j+1} \begin{bmatrix} I_j \\ 0^* \end{bmatrix} = (A - \sigma_1 B)Y_{j+1} \begin{bmatrix} T_j \\ s^* \end{bmatrix}.$$
Introducing the shift $\sigma_2$ this becomes

\begin{equation}
BY_{j+1} \left\{ \begin{bmatrix} I_j & 0^T \\ 0^T & 0^T \end{bmatrix} + (\sigma_1 - \sigma_2) \begin{bmatrix} T_j \\ s^* \end{bmatrix} \right\} = (A - \sigma_2 B)Y_{j+1} \begin{bmatrix} T_j \\ s^* \end{bmatrix}.
\end{equation}

To construct a Krylov–Schur relation we must get rid of the last non-zero row of the matrix in braces in (11.24). To that end we use the QR factorization

\begin{equation}
\begin{bmatrix} I_j & 0^T \\ 0^T & 0^T \end{bmatrix} + (\sigma_1 - \sigma_2) \begin{bmatrix} T_j \\ s^* \end{bmatrix} = Q_{j+1} \begin{bmatrix} R_j \\ 0^T \end{bmatrix}.
\end{equation}

Using it we obtain

\begin{equation}
BY_{j+1}Q_{j+1} \begin{bmatrix} R_j \\ 0^T \end{bmatrix} \equiv BW_{j+1} \begin{bmatrix} R_j \\ 0^T \end{bmatrix} = BW_j R_j = (A - \sigma_2 B)W_{j+1}Q_{j+1} \begin{bmatrix} T_j \\ s^* \end{bmatrix}
\end{equation}

Multiplying with $(A - \sigma_2 B)^{-1}$ from the left we obtain

\begin{equation}
(A - \sigma_2 B)^{-1}BW_j = W_{j+1}Q_{j+1} \begin{bmatrix} T_jR_j^{-1} \\ s^* \end{bmatrix} = W_{j+1} \begin{bmatrix} M_j \\ t^* \end{bmatrix}
\end{equation}

or

\begin{equation}
(A - \sigma_2 B)^{-1}BW_j = W_j M_j + w_{j+1}t^*.
\end{equation}

This equation can easily be transformed into an Arnoldi or Krylov–Schur relation.

All these transformations can be executed without performing any operations on the large sparse matrices $A$ and $B$.

In a practical implementation, the mentioned procedure is combined with locking, purging, and implicit restart. First run shifted and inverted Arnoldi with the first shift $\sigma_1$. When an appropriate number of eigenvalues around $\sigma_1$ have converged, lock these converged eigenvalues and purge those that are altogether outside the interesting region, leaving an Arnoldi (11.22) or Krylov–Schur recursion (11.22) for the remaining vectors. Then introduce the new shift $\sigma_2$ and perform the steps above to get a new basis $W_{j+1}$ that replaces $V_{j+1}$. Start at the new shift by operating on the last vector of this new basis

\[ r := (A - \sigma_2 B)^{-1}Bw_{j+1} \]

and get the next basis vector $w_{j+2}$ in the Arnoldi recurrence with the new shift $\sigma_2$. Continue until we get convergence for a set of eigenvalues around $\sigma_2$, and repeat the same procedure with new shifts until either all interesting eigenvalues have converged or all the shifts in the prescribed frequency range have been used.

CHAPTER 11. RESTARTING ARNOLDI AND LANCZOS ALGORITHMS

Chapter 12

The Jacobi-Davidson Method

The Lanczos and Arnoldi methods are very effective to compute extremal eigenvalues provided these are well separated from the rest of the spectrum. Lanczos and Arnoldi methods combined with a shift-and-invert spectral transformation are also efficient to compute eigenvalues in the vicinity of the shift $\sigma$. In this case it is necessary to solve a system of equation

$$(A - \sigma I)x = y, \quad \text{or} \quad (A - \sigma M)x = y,$$

respectively, in each iteration step. These systems have to be solved very accurately since otherwise the Lanczos or Arnoldi relation does not hold anymore. In most cases the matrix $A - \sigma I$ (or $A - \sigma M$) is LU or Cholesky factored. The Jacobi–Davidson (JD) algorithm is particularly attractive if this factorization is not feasible [11].

12.1 The Davidson algorithm

Let $v_1, \ldots, v_m$ be a set of orthonormal vectors, spanning the search space $R(V_m)$ with $V_m = [v_1, \ldots, v_m]$. In the Galerkin approach we are looking for vectors $s \in \mathbb{R}^m$ such that the Galerkin condition holds,

$$(12.1) \quad AV_m s - \vartheta V_m s \perp v_1, \ldots, v_m.$$  

This immediately leads to the (small) eigenvalue problem

$$(12.2) \quad V^*AV_m s = \vartheta V^*V_m s$$

with solutions $(\vartheta_j^{(m)}, s_j^{(m)}), j = 1, \ldots, m$. $\vartheta_j^{(m)}$ is called a Ritz value and $V_m s_j^{(m)}$ is called a Ritz vector. In the sequel we omit the superscript $m$ for readability. The dimension of the search space should become evident from the context.

Let us consider, say, the Ritz value $\vartheta_j$, its Ritz vector $u_j = V_m s_j$ and their residual $r_j = Au_j - \vartheta_j u_j$. Often we are looking for the largest or smallest eigenvalue of $A$ in which case $j = 1$ or $j = m$, respectively. The question immediately arises how we can improve $(\vartheta_j, u_j)$ if $\|r_j\|$ is still too large. It is straightforward to try to find a better approximate eigenpair by expanding the search space. Davidson, in his original paper [2], suggested to compute a vector $t$ from

$$(12.3) \quad (D_A - \vartheta_j I)t = r_j,$$
where $D_A$ is the diagonal of the matrix $A$. The vector $t$ is then made orthogonal to the basis vectors $v_1, \ldots, v_m$. The resulting vector, after normalization, is chosen as $v_{m+1}$ by which $R(V_m)$ is expanded, i.e., $V_{m+1} = [v_1, \ldots, v_m, v_{m+1}]$.

This method is successful in finding dominant eigenvalues of (strongly) diagonally dominant matrices. The matrix $D_A - \vartheta_jI$ has therefore often been viewed as a preconditioner for the matrix $A - \vartheta_jI$. A number of investigations were made with more sophisticated preconditioners $M - \vartheta_jI$, see e.g. [7, 8]. They lead to the conclusion that $M - \vartheta_jI$ should not be too close to $A - \vartheta_jI$ which contradicts the notion of a preconditioner as being an easily invertible (factorizable) approximation of $A - \vartheta_jI$.

### 12.2 The Jacobi orthogonal component correction

In his seminal paper, Jacobi [6] not only presented the solution of symmetric eigenvalue problems by successive application of (later to be called) Jacobi rotations, but also presented an approach to improve an approximate eigenpair with an iterative procedure. Here, we give Jacobi’s approach in a generalized form presented by Sleijpen and van der Vorst [11]. Let $u_j$ be an approximation to the eigenvector $x$ of $A$ corresponding to the eigenvalue $\lambda$. Jacobi proposed to correct $u_j$ by a vector $t$, $u_j \perp t$, such that

$$A(u_j + t) = \lambda(u_j + t), \quad u_j \perp t. \tag{12.4}$$

This is called the **Jacobi orthogonal component correction** (JOCC) by Sleijpen & van der Vorst [11]. As $t \perp u_j$ we may split equation (12.4) in the part parallel to $u_j$ and in the part orthogonal to $u_j$. If $\|u_j\| = 1$ then the part parallel to $u_j$ is

$$u_j u_j^* A(u_j + t) = \lambda u_j u_j^* (u_j + t) \tag{12.5}$$

which simplifies to the scalar equation

$$\vartheta_j + u_j^* A t = \lambda. \tag{12.6}$$

Here $\vartheta_j$ is the Rayleigh quotient of $u_j$, $\vartheta_j = \rho(u_j)$. The part orthogonal to $u_j$ is

$$ (I - u_j u_j^*) A(u_j + t) = \lambda (I - u_j u_j^*) (u_j + t) \tag{12.7}$$

which is equivalent to

$$ (I - u_j u_j^*) (A - \lambda I) t = (I - u_j u_j^*) (-A u_j + \lambda u_j) = -(I - u_j u_j^*) A u_j = -(A - \vartheta_j I) u_j =: -r_j. $$

As $(I - u_j u_j^*) t = t$ we can rewrite this equation in symmetrized form as

$$ (I - u_j u_j^*) (A - \lambda I) (I - u_j u_j^*) t = -r_j = -(A - \vartheta_j I) u_j, \quad t \perp u_j. \tag{12.8}$$

If $A$ is symmetric then the matrix in (12.8) is symmetric as well.

Unfortunately, we do not know $\lambda$. Therefore, we replace $\lambda$ by $\vartheta_j$ to get the **Jacobi–Davidson correction equation**

$$ (I - u_j u_j^*) (A - \vartheta_j I) (I - u_j u_j^*) t = -r_j = -(A - \vartheta_j I) u_j, \quad t \perp u_j. \tag{12.9}$$

As $r_j \perp u_j$ (in fact $r_j \perp V_m$) this equation is consistent if $A - \vartheta_j I$ is nonsingular.
The correction equation (12.9) is, in general, solved iteratively by the GMRES or MINRES algorithm [1]. Often, only little accuracy in the solution is required.

Once \( t \) is (approximately) known we set

\[
(12.10) \quad u_{j+1} = u_j + t.
\]

From (12.6) we may then obtain

\[
(12.11) \quad \vartheta_{j+1} = \vartheta_j + u_j^* A t.
\]

If \( A \) is symmetric \( \vartheta_{j+1} \) may be set equal to the Rayleigh quotient \( \rho(u_{j+1}). \)

Let us analyze (12.9) more closely. Let us first investigate the role of the orthogonality condition \( t \perp u_j. \) If this condition is omitted then the equation to be solved is

\[
(12.12) \quad (I - u_j u_j^*)(A - \vartheta_j I) t = -r_j = -(A - \vartheta_j I) u_j.
\]

This equation has the solution \( t = -u_j. \) Therefore, without the condition \( t \perp u_j \) there is no progress in solving the eigenvalue problem \( A x = \lambda x. \)

One can argue that this is the approach suggested by Davidson [2]. Davidson approximated \( A \) on the left side of (12.12) by an approximation of it, typically the diagonal, say \( D \), of \( A \). As his matrices were diagonally dominant, he solved a reasonably good approximation of (12.12). If \( D \) in (12.3) is considered a preconditioner of \( A \) then any matrix closer to \( A \) should lead to better performance of the algorithm. In extremis, \( A \) should be a possible choice for the matrix on the left. But we have just seen that this leads to a situation without progress. In fact the progress in the iteration deteriorates the better the ‘preconditioner’ approximates the system matrix. In consequence, \( D \) in (12.3) must not be considered a preconditioner.

Let us now investigate what happens if the correction equation is solved exactly. To that end we write it as

\[
(I - u_j u_j^*)(A - \vartheta_j I) t = -r_j, \quad t \perp u_j,
\]

which immediately leads to

\[
(A - \vartheta_j I) t - u_j u_j^*(A - \vartheta_j I) t = -r_j,
\]

or,

\[
(A - \vartheta_j I) t = \alpha u_j - r_j.
\]

Assuming that \( \vartheta_j \) is not an eigenvalue of \( A \) we get

\[
t = \alpha(A - \vartheta_j I)^{-1} u_j - (A - \vartheta_j I)^{-1} r_j.
\]

The constraint \( u_j^* t = 0 \) allows us to determine the free variable \( \alpha \),

\[
0 = \alpha u_j^*(A - \vartheta_j I)^{-1} u_j - u_j^*(A - \vartheta_j I)^{-1} r_j,
\]

whence

\[
\alpha = \frac{u_j^*(A - \vartheta_j I)^{-1} r_j}{u_j^*(A - \vartheta_j I)^{-1} u_j}.
\]
By (12.10), the next approximate is then
\[ u_{j+1} = u_j + t = u_j + \alpha (A - \vartheta_j I)^{-1} u_j - \left( A - \vartheta_j I \right)^{-1} r_j = \alpha (A - \vartheta_j I)^{-1} u_j \]

which is a step of Rayleigh quotient iteration! This implies a fast (quadratic in general, cubic in the Hermitian case) convergence rate of this algorithm.

In general the correction equation
\[ \hat{\mathbf{A}} t = (I - u_j u_j^*) (A - \vartheta_j I) (I - u_j u_j^*) t = -r_j, \quad t \perp u_j, \]
is solved iteratively with a Krylov space solver like GMRES or MINRES [1]. To get a decent performance a preconditioner is needed. Sleijpen and van der Vorst suggest preconditioners of the form
\[ \hat{\mathbf{K}} = (I - u_j u_j^*) K (I - u_j u_j^*), \quad \hat{\mathbf{K}} \approx A - \vartheta_j I. \]

We assume that \( \hat{\mathbf{K}} \) is (easily) invertible, i.e., that it is computationally much cheaper to solve a system of equation with \( \hat{\mathbf{K}} \) than with \( A \). With this assumption the system of equation
\[ \hat{K} z = v, \quad z \perp u_j, \]
can be solved provided that the right-hand side \( v \) is in the range of \( \hat{K} \), i.e., provided that \( v \perp u_j \). We formally denote the solution by \( z = \hat{K}^+ v \). So, instead of (12.14) we solve the equation
\[ \hat{K}^+ \hat{\mathbf{A}} t = -\hat{K}^+ r_j, \quad t \perp u_j, \]
Let \( t_0 = 0 \) be the initial approximation to the solution of (12.16). (Notice that \( t_0 \) trivially satisfies the orthogonality constraint.) Because of the projectors \( I - u_j u_j^* \) in the definitions of \( \hat{\mathbf{A}} \) and \( \hat{\mathbf{K}} \) all approximations are orthogonal to \( u_j \).

In each iteration step we have to compute
\[ z = \hat{K}^+ \hat{\mathbf{A}} v, \quad z \perp u_j \]
where \( v \perp u_j \). To do this we proceed as follows. First we write
\[ \hat{\mathbf{A}} v = (I - u_j u_j^*) (A - \vartheta_j I) v =: y. \]
Then,
\[ \hat{K} z = y, \quad z \perp u_j. \]
With (12.15) this becomes
\[ (I - u_j u_j^*) \hat{K} z = \hat{K} z - u_j u_j^* \hat{K} z = y, \]
the solution of which is
\[ z = \hat{K}^{-1} y - \alpha \hat{K}^{-1} u_j, \]
where, formally, \( \alpha = -u_j^* \hat{K} z \). Similarly as earlier, we determine the scalar by means of the constraint \( z^* u_j = 0 \). Thus
\[ \alpha = \frac{u_j^* \hat{K}^{-1} y}{u_j^* \hat{K}^{-1} u_j}. \]

Remark 12.1. Since \( u_j \) is fixed during the solution of the secular equation, the vector \( \hat{K}^{-1} u_j \) has to be computed just once. Thus, if the iterative solver needs \( k \) steps until convergence, \( k + 1 \) systems of equations have to be solved with the matrix \( K \).
12.2. THE JACOBI ORTHOGONAL COMPONENT CORRECTION

Algorithm 12.1 The Jacobi–Davidson algorithm to compute the eigenvalue of $A$ closest to a target value $\tau$

1: Let $A, B \in \mathbb{F}^{n \times n}$. This algorithm computes the eigenvalue of $A$ that is closest to $\tau$.
   Let $t$ be an initial vector. Set $V_0 = [], V_0^A = [], m = 0$.
2: loop
   3: for $i = 1, \ldots, m - 1$ do
   4: \hfill $t \leftarrow t - (v_i^*t)v_i$; /* $t = (I - V_{m-1}V_{m-1}^*)t$ */
   5: end for
   6: $v_m \leftarrow t/\|t\|$; $v_m^A := Av_m$; $V_m := [V_{m-1}, v_m]$; $V_m^A := [V_{m-1}^A, v_m^A]$;
   7: for $i = 1, \ldots, m$ do
   8: $M_{i,m} := v_i^*v_m^A$; $M_{m,i} := v_m^*v_i^A$; /* $M = V_m^*AV_m$ */
   9: end for
   10: $M_{m,m} := v_m^*v_m$;
11: Compute the eigenvalue $\vartheta$ of $M$ closest to $\tau$ and the corresponding eigenvector $s$: $Ms = \vartheta s$; $\|s\| = 1$;
12: $u := V_m s$; $u^A := V_m^*s$; $r := u^A - \vartheta u$;
13: if $\|r\| < \text{tol}$ then
14: \hfill return $(\hat{\lambda} = \vartheta, \tilde{x} = u)$
15: end if
16: (Approximately) solve the correction equation for $t$,
   \hfill $(I - uu^*)(A - \vartheta jI)(I - uu^*)t = -r$, \hfill $t \perp u$;
17: end loop

12.2.1 Repeats

Evidently, in Algorithm 12.1, the dimension $m$ of the search space can get large. To limit memory consumption, we limit $m$ such that $m \leq m_{\text{max}}$. As soon as $m = m_{\text{max}}$ we restart: $V_m = V_{m_{\text{max}}}$ is replaced by the $q$ Ritz vectors corresponding to the Ritz values closest to the target $\tau$. Notice that the Schur decomposition of $M = M_{m,m} = V_m^*AV_m$ is computed already in step 11 of the Algorithm. Let $M = S^*TS$ be this Schur decomposition with $|t_{11} - \tau| \leq |t_{22} - \tau| \leq \cdots$. Then we set
   \begin{align*}
   V_q &= V_m \cdot S_{1:q,1:q}, \quad V_q^A = V_m^* \cdot S_{1:q,1:q}, \quad M = T \cdot S_{1:q,1:q}.
   \end{align*}
Notice that the restart is easy because the Jacobi–Davidson algorithm is not a Krylov space method.

12.2.2 The computation of several eigenvalues

Let $\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_k$ be already computed eigenvectors or Schur vectors with $\tilde{x}_i^*\tilde{x}_j = \delta_{ij}$, $1 \leq i, j \leq k$. Then

\begin{equation}
A Q_k = Q_k T_k, \quad Q_k = [\tilde{x}_1, \ldots, \tilde{x}_k].
\end{equation}

is a partial Schur decomposition of $A$ [13]. We want to extend the partial Schur decomposition by one vector employing the Jacobi–Davidson algorithm. Since Schur vectors are mutually orthogonal we can apply the Jacobi–Davidson algorithm in the orthogonal complement of $R(Q_k)$, i.e., we apply the Jacobi–Davidson algorithm to the matrix

\begin{equation}
(I - Q_k Q_k^*) A (I - Q_k Q_k^*)
\end{equation}

$Q_k = [\tilde{x}_1, \ldots, \tilde{x}_k]$. The correction equation gets the form

\begin{equation}
(I - u_j u_j^*)(I - Q_k Q_k^*) (A - \vartheta_j I) (I - Q_k Q_k^*) (I - u_j u_j^*) t = -r_j, \quad t \perp u_j, t \perp Q_k.
\end{equation}
222

CHAPTER 12. THE JACOBI-DAVIDSON METHOD

As $u_j \perp Q_k$ we have

$$(I - u_ju_j^*)(I - Q_kQ_k^*) = I - \tilde{Q}_k\tilde{Q}_k^*, \quad \tilde{Q}_k = [\tilde{x}_1, \ldots, \tilde{x}_k, u_j].$$

Thus, we can write (12.19) in the form

(12.20) $$(I - \tilde{Q}_k\tilde{Q}_k^*)(A - \vartheta_j I)(I - \tilde{Q}_k\tilde{Q}_k^*)t = -r_j, \quad \tilde{Q}_k t = 0.$$  

The preconditioner becomes

(12.21) $\tilde{K} = (I - \tilde{Q}_k\tilde{Q}_k^*)K(I - \tilde{Q}_k\tilde{Q}_k^*), \quad K \approx A - \vartheta_j I.$

Similarly as earlier, for solving $\tilde{K}z = \tilde{A}v$, $\tilde{Q}_k^*z = 0$, we execute the following steps. Since $\tilde{A}v = (I - \tilde{Q}_k\tilde{Q}_k^*) (A - \vartheta_j I)v =: (I - \tilde{Q}_k\tilde{Q}_k^*)y =: y - \tilde{Q}_k\tilde{Q}_k^*y\cdot\mathbf{a}$, we have to solve

$$\tilde{K}z = (I - \tilde{Q}_k\tilde{Q}_k^*)Kz = (I - \tilde{Q}_k\tilde{Q}_k^*)y, \quad z \perp \tilde{Q}_k.$$  

Thus,

$$z = K^{-1}y - K^{-1}\tilde{Q}_k\mathbf{a}.$$  

Similarly as earlier, we determine $\mathbf{a}$ by means of the constraint $\tilde{Q}_k^*z = 0$,

$$\mathbf{a} = (\tilde{Q}_kK^{-1}\tilde{Q}_k)^{-1}\tilde{Q}_k^*K^{-1}y.$$  

If the iteration has converged to the vector $\tilde{x}_{k+1}$ we can extend the partial Schur decomposition (12.17). Setting $Q_{k+1} := [Q_k, \tilde{x}_{k+1}]$, we get

(12.22) $AQ_{k+1} = Q_{k+1}T_{k+1}$

with

$$T_{k+1} = \begin{bmatrix} T_k & \tilde{Q}_k^*A\tilde{x}_{k+1} \\ 0 & \tilde{x}_{k+1}^*A\tilde{x}_{k+1} \end{bmatrix}.$$  

12.2.3 Spectral shifts

In the correction equation (12.9) and implicitly in the preconditioner (12.15) a spectral shift $\vartheta_j$ appears. Experiments show that it is not wise to always choose the Rayleigh quotient of the recent eigenvector approximation $u$ as the shift. In particular, far away from convergence, i.e., in the first few iteration steps, the Rayleigh quotient may be far away from the (desired) eigenvalue, and in fact may direct the JD iteration to an unwanted solution. So, one proceeds similarly as in the plain Rayleigh quotient iteration, cf. Remark 7.6 on page 143. Initially, the shift is held fixed, usually equal to the target value $\tau$. As soon as the norm of the residual is small enough, the Rayleigh quotient of the actual approximate is chosen as the spectral shift in the correction equation. For efficiency
12.2. THE JACOBI ORTHOGONAL COMPONENT CORRECTION

Algorithm 12.2 The Jacobi–Davidson QR algorithm to compute $p$ of the eigenvalues closest to a target value $\tau$

1: $Q_0 := []$; $k = 0$. /* Initializations */
2: Choose $v_1$ with $\|v_1\| = 1$.
3: $w_1 = A v_1$; $H_1 := v_1^* w_1$; $V_1 := [v_1]$; $W_1 := [W_1]$;
4: $\tilde{q} = v_1$; $\tilde{\vartheta} = v_1^* w_1$; $r := w_1 - \tilde{\vartheta} \tilde{q}$.
5: $j := 1$; 
6: while $k < p$ do
7: /* Compute Schur vectors one after the other */
8: Approximatively solve the correction equation for $t$

$$(I - \tilde{Q}_k \tilde{Q}_k^*)(A - \tilde{\vartheta} I)(I - \tilde{Q}_k \tilde{Q}_k^*)t = -r_j, \quad \tilde{Q}_k^* t = 0.$$ 

where $\tilde{Q}_k = [Q_k, \tilde{q}]$.
9: $v_j = (I - V_{j-1} V_{j-1}^*) t / \| (I - V_{j-1} V_{j-1}^*) t \|$; $V_j := [V_{j-1}, v_j]$.
10: $w_j = A v_j$; $H_j = \begin{bmatrix} H_{j-1} & V_{j-1}^* w_j \\ v_j^* W_{j-1} & v_j^* w_j \end{bmatrix}$; $W_j = [W_{j-1}, w_j]$.
11: Compute the Schur decomposition of $H_j =: S_j R_j S_j$ with the eigenvalues $r_{ii}^{(j)}$ sorted according to their distance to $\tau$.
12: /* Test for convergence */
13: repeat
14: $\tilde{\vartheta} = \Lambda_1^{(j)}$; $\tilde{q} = V_j s_1$; $\tilde{w} = W_j s_1$; $r = \tilde{w} - \tilde{\vartheta} \tilde{q}$
15: found := $\| r \| < \varepsilon$
16: if found then
17: $Q_{k+1} = [Q_k, \tilde{q}]$; $k := k + 1$
18: end if
19: until not found
20: /* Restart */
21: if $j = j_{\text{max}}$ then
22: $V_{j_{\text{min}}} := V_j[s_1, \ldots, s_{\text{min}}]$; $T_{j_{\text{min}}} := T_j(1 : \text{min}, 1 : \text{min})$;
23: $H_{j_{\text{min}}} := T_{j_{\text{min}}}$; $S_{j_{\text{min}}} := I_{j_{\text{min}}}$; $J := j_{\text{min}}$
24: end if
25: end while

reasons, the spectral shift in the preconditioner $K$ is always fixed. In this way it has to be computed just once. Notice that $\tilde{K}$ is changing with each correction equation.

Remark 12.2. As long as the shift is held fixed Jacobi–Davidson is actually performing a shift-and-invert Arnoldi iteration. □

Algorithm 12.2 gives the framework for an algorithm to compute the partial Schur decomposition of a matrix $A$. $Q_k$ stores the converged Schur vectors; $V_j$ stores the ‘active’ search space. This algorithm does not take into account some of the just mentioned issues. In particular the shift is always taken to be the Rayleigh quotient of the most recent approximate $\tilde{q}$. 
CHAPTER 12. THE JACOBI-DAVIDSON METHOD

12.3 The generalized Hermitian eigenvalue problem

We consider the problem

\[ Ax = \lambda M x, \]

with \( A \) and \( M \) \( n \times n \) Hermitian, and \( M \) additionally positive definite. Then the eigenvectors can be chosen mutually \( M \)-orthogonal,

\[ x_i^* M x_j = \delta_{ij}, \quad Ax_i = \lambda_i M x_i, \quad 1 \leq i, j \leq n, \]

where \( \delta_{ij} \) denotes the Kronecker delta function. Then it makes sense in the Jacobi–Davidson (as in other algorithms) to keep the iterates \( M \)-orthogonal.

Let \( V_m = [v_1, \ldots, v_m] \) be an \( M \)-orthogonal basis of the search space \( V_m \). Then the Galerkin condition

\[ AV_m s - \vartheta MV_m s \perp v_1, \ldots, v_m, \]

leads to the eigenvalue problem

\[ V_m^* AV_m s = \vartheta V_m^* MV_m s = \vartheta s. \]

Let \( (\tilde{\vartheta}, \tilde{u}) = V_m \tilde{s} \) be a solution of \((12.26)\). Then the correction \( t \) to \( \tilde{u} \) must be \( M \)-orthogonal,

\[ t^* M \tilde{u} = 0 \iff (I - \tilde{u}\tilde{u}^* M)t = t. \]

The correction equation in turn becomes

\[ (I - M\tilde{u}\tilde{u}^*)(A - \tilde{\vartheta}M)(I - \tilde{u}\tilde{u}^* M)t = -(I - \tilde{u}\tilde{u}^* M)\tilde{r}, = -\tilde{r}, \quad t \perp_M \tilde{u}, \]

where \( \tilde{r} = A\tilde{u} - \tilde{\vartheta}M\tilde{u} \). Preconditioners for the secular equation are chosen of the form

\[ K = (I - M\tilde{u}\tilde{u}^*)K(I - \tilde{u}\tilde{u}^* M), \]

where \( K \approx A - \tau M \) and \( \tau \) is the target value.

12.4 A numerical example

We give a demonstration on how a full-fledged Jacobi–Davidson algorithm works. The code is a MATLAB implementation of a program from the PhD thesis of Geus [4]. It solves the generalized symmetric eigenvalue problem as discussed in the previous section. The command \texttt{help jdsym} provides the output given on page 225.

As the numerical example we again consider the acoustic behaviour in the interior of a car. We compute the five smallest eigenvalues and associated eigenvectors. The preconditioner is chosen to be the diagonal of \( A \). An eigenpair \((\tilde{\lambda}, \tilde{q}) \) is declared converged if the residual norm \( \|A\tilde{q} - \tilde{\lambda}M\tilde{q}\| < 10^{-8}\|\tilde{q}\| \). Most of the components of \texttt{options} are explained in the help text. The residual norms for each iteration step are plotted in Fig. 12.1. As soon as an eigenpair has converged a new iteration starts. The residual norm then increases by several orders of magnitude.
12.4. A NUMERICAL EXAMPLE

\[ Q, \lambda, \text{it} = \text{jdsym}(n, A, B, K, kmax, \tau, \text{options}) \]

jdsym is a MATLAB implementation of the JDQR algorithm for symmetric matrices.

jdsym returns \( kmax \) eigenvalues with corresponding eigenvectors of the matrix \( A \) near the target \( \tau \). \( K \) is a symmetric preconditioner for \( A - \tau B \).

The arguments \( A \) and \( B \) both contain either \( n \)-by-\( n \) symmetric matrices or a string containing the name of an M-file which applies a symmetric linear operator to the columns of a given matrix. Matrix \( B \) must be positive definite.

To solve the specialized eigenvalue problem \( A \times x = \lambda \times x \) pass an empty matrix \( [] \) for parameter \( B \). If no preconditioner is used pass an empty matrix \( [] \) for parameter \( K \).

The options structure specifies certain parameters in the algorithm:

- **options.tol**: convergence tolerance, \( 1e^{-10} \)
- **options.jmax**: maximal dimension of search subspace \( V \), \( 2 \times kmax \)
- **options.jmin**: dimension of search subspace \( V \) after restart, \( kmax \)
- **options.maxit**: maximum number of outer iterations, \( \max(100, 2n/jmax) \)
- **options.clvl**: verbosity of output (0 means no output), 1
- **options.eps_tr**: tracing parameter as described in literature, \( 1e^{-4} \)
- **options.toldecay**: convergence tolerance for inner iteration is \( \text{toldecay}^{(-\text{solvestep})} \)
- **options.cgmaxit**: maximum number of iterations in linear solver, 100
- **options.V0**: initial search subspace, \( \text{rand}(n,1) - .5 \)
- **options.linsolv**: solver used for corrections equation, 1
  - 1 -- CGS
  - 2 -- SYMMLQ
  - 3 -- CGS_OP
  - 4 -- CGS mit SYMOP
  - 5 -- MINRES
  - 6 -- QMR
  - 7 -- QMRS
- **options.strategy**: strategy to avoid computation of zero eigenvalues:
  - 0 -- standard JD algorithm
  - 1 -- never choose Ritz values that are close to zero as best current approximation.
    Purge Ritz values that are close to zero when restarting
  - 2 -- dynamically adjust \( \tau \)
  - 3 -- see (1) and set \( \tau \) to last converged eigenvalue if it was bigger than the old \( \tau \)
  - 4 -- set \( \tau \) to last converged eigenvalue if it was bigger than the old \( \tau \)

The converged eigenvalues and eigenvectors are stored in \( Q \) and \( \lambda \). The number of outer JD iterations performed is returned in \( \text{it} \).

Figure 12.1: Jacobi–Davidson convergence history
12.5 The Jacobi–Davidson algorithm for interior eigenvalues

Interior eigenvalues are eigenvalues that do not lie at the ‘border’ of the convex hull of the spectrum, cf. Fig. 12.2

Figure 12.2: View of a spectrum $\sigma(A)$ in the complex plane. The eigenvalues in the red circle are to be computed

The success of the Jacobi–Davidson algorithm depends heavily on the quality of the actual Ritz pair $(\tilde{\vartheta}_j, \tilde{q})$. However, the Rayleigh–Ritz procedure can lead to problem if it is applied to interior eigenvalues. The following simple numerical example shall demonstrate the problem. Let

$$A = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix}, \quad U = \begin{bmatrix} 1 & 0 \\ 0 & \sqrt{0.5} \\ 0 & \sqrt{0.5} \end{bmatrix}.$$  

Then,

$$U^*AU = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}, \quad U^*U = I_2.$$  

So, any linear combination of the columns of $U$ is a Ritz vector corresponding to the Ritz value 0, e.g.,

$$U \begin{bmatrix} \sqrt{0.5} \\ 0.5 \end{bmatrix} = \begin{bmatrix} \sqrt{0.5} \\ 0.5 \end{bmatrix}.$$  

Thus, although the basis contains the correct eigenvalue associated with the eigenvalue 0, the Rayleigh–Ritz procedure fails to find it and, instead, returns a very bad eigenvector approximation.

This example may look contrived. So, we conduct a MATLAB experiment with the same $A$ but with a randomly perturbed $U$. 
12.6 Harmonic Ritz values and vectors

In the shift-and-invert Arnoldi algorithm the basic operator is \( A - \sigma I \) where \( \sigma \) is some shift. The Arnoldi algorithm finds the largest eigenvalues of \( A - \sigma I \), i.e., the eigenvalues of \( A \) closest to the shift. One of the reasons for inventing the Jacobi-Davidson algorithm is infeasibility of the factorization of \( A - \sigma I \). Therefore, a shift-and-invert approach is not possible.

A clever way out of this dilemma works as follows: We apply the Ritz–Galerkin procedure with the matrix \((A - \sigma I)^{-1}\) and some subspace \( \mathcal{R}(V) \subset \mathbb{F}^n \). This leads to the
CHAPTER 12. THE JACOBI-DAVIDSON METHOD

eigenvalues problem

(12.30) \[ V^*(A - \sigma I)^{-1}V s = \mu V^*Vs. \]

The largest Ritz values \( \mu_j \) approximate the largest eigenvalues of \((A - \sigma I)^{-1}\), i.e.,

\[ \mu_j \approx \frac{1}{\lambda_j - \sigma} \iff \lambda_j \approx \sigma + \frac{1}{\mu_j}, \]

where \( \lambda_j \) is an eigenvalue of \( A \) close to the shift \( \sigma \).

The trick is in the choice of \( V \). Let us set \( V := (A - \sigma I)U \). Then (12.30) becomes

(12.31) \[ U^*(A - \sigma I)^*Us = \mu U^*(A - \sigma I)^*(A - \sigma I)Us, \]

or, with \( \tau = 1/\mu \),

(12.32) \[ U^*(A - \sigma I)^*(A - \sigma I)Us = \tau U^*(A - \sigma I)^*Us. \]

With \( V = (A - \sigma I)U \) this becomes

(12.33) \[ V^*Vs = \tau V^*Us. \]

If \( A \) is nonsymmetric, we compute an orthonormal basis \( \tilde{V} \) of \( V = (A - \sigma I)U \). Then we can write (12.32) in the nonsymmetric form

(12.34) \[ \tilde{V}^*(A - \sigma I)Us = \tau \tilde{V}^*Us. \]

We make the following

**Definition 12.1** Let \((\tau, s)\) be an eigenpair of (12.32)-(12.34). Then the pair \((\sigma + \tau, Us)\) is called a **harmonic Ritz pair** of \( A \) with shift \( \sigma \).

In practice, we are interested only in the harmonic Ritz pair corresponding to the smallest harmonic Ritz values. In the correction equation of the Jacobi–Davidson algorithm the harmonic Ritz vector is used as the latest eigenvector approximation and the harmonic Ritz values as the shift. In the symmetric case the harmonic Ritz value is replaced by the Rayleigh quotient of the harmonic Ritz vector \( x \), since

\[ \|Ax - \rho(x)x\| \leq \|Ax - \mu x\|, \quad \text{for all } \mu. \]

We continue the previous numerical example regarding the computation of the eigenvalue 0 of \( A = \text{diag}(0, 1, -1) \)

\[
\begin{align*}
&> \text{V=(A-theta*eye(3))*U1; } \\
&> \text{[v,l]=eig(V'*V, V'*U1)} \\
&v = \\
&-1.000000000000000 \quad -1.000000000000000 \\
&0.000000000000000 \quad -0.713473633096137 \\
&l = \\
&1.0e+17 * \\
&0.000000000000000 \quad 0 \\
&0 \quad -1.970695224946170 \\
&\end{align*}
\]

\[
\begin{align*}
&> \text{theta + l(1,1) } \quad \% \text{ Harmonic Ritz value} \\
&\text{ans =} \\
&3.722769433847084e-05
\end{align*}
\]
12.7. Refined Ritz vectors

An alternative to harmonic Ritz vectors are refined Ritz vectors [13]. Again we start from the observation that the Ritz values were of good quality. What we need are improved Ritz vectors. Stewart [13] suggested the following procedure.

**Definition 12.2** Let \( \mu_\vartheta \) be a Ritz value of \( A \) restricted to \( U_\vartheta \). A solution of the minimization problem

\[
(12.35) \min_{\hat{x} \in U_\vartheta, \|\hat{x}\| = 1} \|A\hat{x} - \mu_\vartheta \hat{x}\|
\]

is called a **refined Ritz vector**.

How is this minimization problem solved? We write \( \hat{x} = U_\vartheta z \). Then (12.35) becomes

\[
(12.36) \min_{\|z\| = 1} \|(A - \mu_\vartheta I)U_\vartheta z\|.
\]

This minimization problem is solved by the right singular vector corresponding to the smallest singular value of \( (A - \mu_\vartheta I)U_\vartheta \) or, equivalently, the eigenvector corresponding to the smallest eigenvalue of

\[
U_\vartheta^* (A - \mu_\vartheta I)^* (A - \mu_\vartheta I)U_\vartheta z = \tau z.
\]

We continue the example of before.

\[
\gg [u,s,v]=svd((A - 0*eye(3))*U)
\]

\[
u =
\]

The above considerations affect the Jacobi–Davidson algorithm in the extraction phase. Steps 11 and 14 in Algorithm 12.2 become

11: Compute the smallest eigenpair \((\tilde{\tau}, \tilde{s})\) of

\[
(W_j^* - \tilde{\sigma} V_j^*)(W_j - \sigma V_j)s = \tau (W_j^* - \tilde{\sigma} V_j^*)V_j s.
\]

14: Set \( \tilde{q} = V_j s \), \( \tilde{w} = W_j s \). \( \tilde{\vartheta} = \sigma + \tau \) or \( \tilde{\vartheta} = \tilde{q}^* A \tilde{q} / \tilde{q}^* \tilde{q} \).

To solve the eigenvalue problem (12.34) the QZ algorithm has to be employed, see section 12.8. In the symmetric case (12.33) the symmetric QR algorithm will suffice in general since the matrix on the left is positive definite.
\[ A = \begin{bmatrix} 0 & 1.0000 & 0 \\ -0.7071 & 0 & 0.7071 \\ 0.7071 & 0 & 0.7071 \end{bmatrix} \]

\[ s = \begin{bmatrix} 1.0000 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \]

\[ v = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix} \]

\[ U_1 v(:,2) \]

\[ \begin{bmatrix} 1.00009500829405 \\ -0.00001878470226 \\ 0.00001878647014 \end{bmatrix} \]

With the refined Ritz vector approach Steps 11 and 14 in Algorithm 12.2 are replaced by

11: Compute the Ritzpair \( (\tilde{\vartheta}, \tilde{q}) \) of \( A \) closest to the target value.
Compute the smallest singular vector \( \tilde{s} \) of \( AV_j - \tilde{\vartheta} V_j \).

14: Replace \( \tilde{q} \) by \( V_j \tilde{s} \).
12.8  The generalized Schur decomposition

The QZ algorithm computes the following generalized Schur decomposition.

**Theorem 12.3 (Generalized Schur decomposition)** If $A, B \in \mathbb{C}^{n \times n}$ then there are unitary matrices $Q, Z \in \mathbb{C}^{n \times n}$ such that
\begin{align}
Q^*AZ &= T^A, \\
Q^*BZ &= T^B,
\end{align}
are upper triangular. If for some $k$, $t_{kk}^A = t_{kk}^B = 0$ then $\sigma(A, B) = \mathbb{C}$. Otherwise
\[\sigma(A, B) = \{t_{ii}^A/t_{ii}^B \mid t_{ii}^B \neq 0\} \cup \sigma(A, B)\]

**Proof.** See [5]

The algorithm starts out with transforming $A$ and $B$ in Hessenberg and upper triangular form, respectively. After defailing zeros in the lower offdiagonal of the Hessenberg matrix and on the diagonal of the upper triangular matrix, the QR algorithm with implicit shifts is applied to $AB^{-1}$. For details see [3].

Corresponding to the notion of an invariant subspace for a single matrix we have the notion of a **deflating subspace** for the pencil $A - \lambda B$. In particular, we say that a $k$-dimensional subspace $S \subset \mathbb{F}^n$ is “deflating” for the pencil $A - \lambda B$ if the subspace $\{Ax + By \mid x, y \in S\}$ has dimension $k$ or less. Note that the columns of the matrix $Z$ in the generalized Schur decomposition define a family of deflating subspaces, for if $Q = [q_1, \ldots, q_n]$ and $Z = [z_1, \ldots, z_n]$ then we have $\text{span}\{Az_1, \ldots, Az_k\} \subset \text{span}\{q_1, \ldots, q_k\}$ and $\text{span}\{Bz_1, \ldots, Bz_k\} \subset \text{span}\{q_1, \ldots, q_k\}$.

12.9  JDQZ: Computing a partial QZ decomposition by the Jacobi–Davidson algorithm

We now consider the generalized eigenvalue problem
\begin{align}
Ax &= \lambda Bx,
\end{align}
with arbitrary $A$ and $B$. There is a variant of Jacobi–Davidson called JDQZ that computes a **partial** QZ decomposition of the stencil $(A, B)$. This section follows closely the corresponding section in the eigenvalue templates [12]. Further details are found in [3].

With $\lambda = \alpha/\beta$, the generalized eigenproblem (12.38) is equivalent to the eigenproblem
\begin{align}
(\beta A - \alpha B)x &= 0,
\end{align}
where we denote a generalized eigenvalue of the matrix pair $\{A, B\}$ as a pair $(\alpha, \beta)$. The notation (12.39) is preferred over (12.40), because underflow or overflow for $\lambda = \alpha/\beta$ in finite precision arithmetic may occur when $\alpha$ and/or $\beta$ are zero or close to zero. It also emphasizes the symmetry of the roles of $A$ and $B$.

A **partial generalized Schur** form of dimension $k$ for a matrix pair $\{A, B\}$ is the decomposition
\begin{align}
AQ_k &= Z_kR_k^A, \\
BQ_k &= Z_kR_k^B,
\end{align}
where $Q_k$ and $Z_k$ are unitary $n \times k$ matrices and $R_k^A$ and $R_k^B$ are upper triangular $k \times k$ matrices. A column $q_i$ of $Q_k$ is referred to as a generalized Schur vector, and we refer to a
pair \((\alpha_i, \beta_i), q_i\), with \((\alpha_i, \beta_i) = (R_k^A(i, i), R_k^B(i, i))\) as a generalized Schur pair. It follows that if \((\alpha, \beta), y\) is a generalized eigenpair of \((R_k^A, R_k^B)\) then \((\alpha, \beta), Q_k y\) is a generalized eigenpair of \(\{A, B\}\).

From the relations \((12.40)\) we see that

\[
\beta_i A q_i - \alpha_i B q_i \perp z_i.
\]

This somewhat resembles the Schur decomposition, where \(A q_i - \lambda_i q_i \perp q_i\). The \(z_i\) on the right hand side suggests that we should follow a Petrov-Galerkin condition for the construction of reduced systems. In each step the approximate eigenvector \(u\) is selected from a \(j\)-dimensional search subspace \(\text{span}(V_j) = \text{span}\{v_1, \ldots, v_j\}\). We require that the residual \(\eta A u - \zeta B u\) is orthogonal to some other well-chosen test subspace \(\text{span}(W_j) = \text{span}\{w_1, \ldots, w_j\}\),

\[
(12.41) \quad \eta A u - \zeta B u \perp \text{span}(W_j).
\]

Equation \((12.41)\) leads to the projected generalized \(j \times j\) eigenproblem

\[
(12.42) \quad (\eta W_j^T AV_j - \zeta W_j^T BV_j) s = 0.
\]

The \(j\)-dimensional pencil \(\eta W_j^T AV_j - \zeta W_j^T BV_j\) can be reduced by the QZ algorithm (see §12.8) to generalized Schur form. This leads to orthogonal \(j \times j\) matrices \(S^R\) and \(S^L\) and upper triangular \(j \times j\) matrices \(T^A\) and \(T^B\), such that

\[
(12.43) \quad (S^L)^*(W_j^T AV_j)S^R = T^A \quad \text{and} \quad (S^L)^*(W_j^T BV_j)S^R = T^B.
\]

This decomposition can be reordered such that the first column of \(S^R\) and the \((1, 1)\)-entries of \(T^A\) and \(T^B\) represent the wanted Petrov solution [3]. With \(s := s^R_1 := S^R e_1\) and \(\zeta := T_{11}^A, \eta := T_{11}^B\), the Petrov vector is defined as

\[
u := V_j s = V_j s^R_1
\]

for the associated generalized Petrov value \((\zeta, \eta)\). In an analogous way we can define a left Petrov vector as

\[
p := W_j s^L_1 \quad \quad s^L_1 := S^L e_1
\]

If \(V_j\) and \(W_j\) are unitary, as in Algorithm 12.3, then \(\|s^R\|_2 = \|s^L\|_2 = 1\) implies \(\|u\|_2 = 1\).

With the decomposition in \((12.43)\), we construct an approximate partial generalized Schur form (cf. \((12.40)\)): \(V_j S^R\) approximates a \(Q_k\), and \(W_j S^L\) approximates the associated \(Z_j\).

It is not yet clear how to choose the test space \(W_j\). The equations \(\text{span}(Z_j) = \text{span}(AQ_j) = \text{span}(BQ_j)\), cf. \((12.40)\), suggest to choose \(W_j\) such that \(\text{span}(W_j)\) coincides with \(\text{span}(\nu_0 AV_j + \mu_0 BV_j)\) for some suitably chosen \(\nu_0\) and \(\mu_0\). With the weights \(\nu_0\) and \(\mu_0\) we can influence the convergence of the Petrov values. If we want eigenpair approximations for eigenvalues \(\lambda\) close to a target \(\tau\), then the choice

\[
\nu_0 = 1/\sqrt{1 + |\tau|^2}, \quad \mu_0 = -\sqrt{1 + |\tau|^2}
\]

is very effective [3], especially if we want to compute eigenvalues in the interior of the spectrum of \(A - \lambda B\). We will call the Petrov approximations for this choice the harmonic Petrov eigenpairs. The Jacobi-Davidson correction equation for the component \(t \perp u\) for the pencil \(\eta A - \zeta B\) becomes

\[
(12.44) \quad (I - pp^*) (\eta A - \zeta B) (I - uu^*) t = -r, \quad r := \eta Au - \zeta Bu.
\]
12.9. JDQZ: COMPUTING A PARTIAL QZ DECOMPOSITION

Sleijpen et al. [10] have shown that if (12.44) is solved exactly, the convergence to the generalized eigenvalue is quadratic. Usually, this correction equation is solved only approximately, for instance, with a (preconditioned) iterative solver. The obtained vector \( \mathbf{t} \) is used for the expansion \( \mathbf{v} \) of \( V_j \) and \( \nu_0 \mathbf{A} \mathbf{v} + \mu_0 \mathbf{B} \mathbf{v} \) is used for the expansion of \( W_j \). For both spaces we work with orthonormal bases. Therefore, the new columns are orthonormalized with respect to the current basis by a modified Gram-Schmidt orthogonalization process.

12.9.1 Restart

Suppose that the generalized Schur form (12.43) is ordered with respect to \( \tau \) such that
\[
|T_{11}^A/T_{11}^B - \tau| \leq |T_{22}^A/T_{22}^B - \tau| \leq \cdots \leq |T_{jj}^A/T_{jj}^B - \tau|,
\]
where \( j \) is the dimension of \( \text{span}(V_j) \). Then, for \( i < j \), the space \( \text{span}(V_i s_i^R, \ldots, V_j s_j^R) \) spanned by the first \( i \) columns of \( V_j s_i^R \) contains the \( i \) most promising Petrov vectors.

The corresponding test subspace is given by \( \text{span}(W_j s_j^L, \ldots, W_i s_i^L) \). Therefore, in order to reduce the dimension of the subspaces (“implicit restart”) to \( j_{min} \), \( j_{min} < j \), the columns \( v_{j_{min}+1} \) through \( v_j \) and \( w_{j_{min}+1} \) through \( w_j \) can simply be discarded and the Jacobi-Davidson algorithm can be continued with
\[
V = [V s_1^R, \ldots, V s_{j_{min}}^R] \quad \text{and} \quad W = [W s_1^L, \ldots, W s_{j_{min}}^L].
\]

12.9.2 Deflation

Like in the Jacobi-Davidson algorithm for the standard eigenvalue problem, in the Jacobi-Davidson process for the generalized eigenvalue problem found (converged) Ritz (here Petrov) vectors can be deflated.

The partial generalized Schur form can be obtained in a number of successive steps. Suppose that we have already available the partial generalized Schur form \( AQ_{k-1} = Z_{k-1} R_{k-1}^A \) and \( BQ_{k-1} = Z_{k-1} R_{k-1}^B \). We want to expand this partial generalized Schur form with the new right Schur vector \( \mathbf{u} \) and the left Schur vector \( \mathbf{p} \) to
\[
A[Q_{k-1} \mathbf{u}] = [Z_{k-1} \mathbf{p}] \begin{bmatrix} R_{k-1}^A & \mathbf{a} \\ 0 & \alpha \end{bmatrix}
\]
and
\[
A[Q_{k-1} \mathbf{u}] = [Z_{k-1} \mathbf{p}] \begin{bmatrix} R_{k-1}^B & \mathbf{b} \\ 0 & \beta \end{bmatrix}
\]
The new generalized Schur pair \( ((\alpha, \beta), \mathbf{u}) \) satisfies
\[
Q_{k-1}^* \mathbf{u} = \mathbf{0} \quad \text{and} \quad (\beta \mathbf{A} - \alpha \mathbf{B}) \mathbf{u} - Z_{k-1} (\beta \mathbf{a} - \alpha \mathbf{b}) = \mathbf{0},
\]
or, since \( \beta \mathbf{a} - \alpha \mathbf{b} = Z_{k-1}^* (\beta \mathbf{A} - \alpha \mathbf{B}) \mathbf{u} \),
\[
Q_{k-1}^* \mathbf{u} = \mathbf{0} \quad \text{and} \quad (I - Z_{k-1} Z_{k-1}^*) (\beta \mathbf{A} - \alpha \mathbf{B}) (I - Q_{k-1} Q_{k-1}^*) \mathbf{u} = \mathbf{0}.
\]
Hence, the vectors \( \mathbf{a} \) and \( \mathbf{b} \) can be computed from
\[
\mathbf{a} = Z_{k-1}^* \mathbf{A} \mathbf{u} \quad \text{and} \quad \mathbf{b} = Z_{k-1}^* \mathbf{B} \mathbf{u}.
\]
Furthermore, the generalized Schur pair \(((\alpha, \beta), u)\) is an eigenpair of the deflated matrix pair

\[
\left( (I - Z_{k-1}Z_{k-1}^*) A (I - Q_{k-1}Q_{k-1}^*) , (I - Z_{k-1}Z_{k-1}^*) B (I - Q_{k-1}Q_{k-1}^*) \right).
\]

This eigenproblem can be solved again with the Jacobi-Davidson QZ process. In that process we construct vectors \(v_i\) that are orthogonal to \(Q_{k-1}\) and vectors \(w_i\) that are orthogonal to \(Z_{k-1}\). This simplifies the computation of the interaction matrices \(M^A\) and \(M^B\), associated with the deflated operators

\[
\begin{align*}
M^A &\equiv W^* (I - Z_{k-1}Z_{k-1}^*) A (I - Q_{k-1}Q_{k-1}^*) V = W^* AV, \\
M^A &\equiv W^* (I - Z_{k-1}Z_{k-1}^*) B (I - Q_{k-1}Q_{k-1}^*) V = W^* BV, \\
\end{align*}
\]

and \(M^A\) and \(M^B\) can be simply computed as \(W^* AV\) and \(W^* BV\), respectively.

### 12.9.3 Algorithm

The Jacobi-Davidson algorithm to compute a partial QZ decomposition for a general matrix pencil \((A, B)\) is given in Algorithm 12.3. This algorithm attempts to compute the generalized Schur pairs \(((\alpha, \beta), q)\), for which the ratio \(\beta/\alpha\) is closest to a specified target value \(\tau\) in the complex plane. The algorithm includes restart in order to limit the dimension of the search space, and deflation with already converged left and right Schur vectors.

To apply this algorithm we need to specify a starting vector \(v_0\), a tolerance \(\epsilon\), a target value \(\tau\), and a number \(k_{\text{max}}\) that specifies how many eigenpairs near \(\tau\) should be computed. The value of \(j_{\text{max}}\) specifies the maximum dimension of the search subspace. If it is exceeded then a restart takes place with a subspace of dimension \(j_{\text{min}}\).

On completion the \(k_{\text{max}}\) generalized eigenvalues close to \(\tau\) are delivered, and the corresponding reduced Schur form \(A_Q = Z R^A, B_Q = Z R^B\), where \(Q\) and \(Z\) are \(n\) by \(k_{\text{max}}\) orthogonal and \(R^A, R^B\) are \(k_{\text{max}}\) by \(k_{\text{max}}\) upper triangular. The generalized eigenvalues are the on-diagonals of \(R^A\) and \(R^B\). The computed form satisfies \(\|A q_j - Z R^A \epsilon_j\|_2 = O(\epsilon), \|B q_j - Z R^B \epsilon_j\|_2 = O(\epsilon)\), where \(q_j\) is the \(j\)th column of \(Q\).

### 12.10 Jacobi-Davidson for nonlinear eigenvalue problems

Nonlinear eigenvalue problems have the form

\[
T(\lambda)x = 0
\]

where the \(n \times n\) matrix \(T(\lambda)\) has elements that depend on the scalar parameter \(\lambda\). For the linear eigenvalue problem \(T(\lambda) = A - \lambda B\). \(\lambda\) is an eigenvalue of (12.45) if \(T(\lambda)\) is singular; a nontrivial solution \(x\) of the singular linear system is a corresponding eigenvector.

For small problems, Newton iteration is applicable. Ruhe [9] suggests to proceed as follows. Complement (12.45) by a normalization condition

\[
v^* x = 1.
\]

Then, we solve

\[
P \begin{pmatrix} x \\ \lambda \end{pmatrix} = \begin{pmatrix} T(\lambda)x \\ v^* x - 1 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}.
\]
Algorithm 12.3 Jacobi–Davidson QZ method for $k_{\text{max}}$ interior eigenvalues close to $\tau$ for the generalized non-Hermitian eigenvalue problem

1: Let $A, B \in \mathbb{C}^{m \times n}$ be non-Hermitian. This algorithm computes $k_{\text{max}}$ interior eigenvalues of $\alpha A x = \beta B x$ close to the target $\tau$.
2: $t = v_0; \quad k = 0; \quad \nu_0 = 1/\sqrt{1 + |\tau|^2}; \quad \mu_0 = -\tau \nu_0; \quad m = 0;$
3: $Q = []; \quad Z = []; \quad S = []; \quad T = []$;
4: while $k < k_{\text{max}}$ do
5: Orthogonalize $t := t - V_m V_m^* t$
6: $m = m + 1; \quad v_m = t/\|t\|; \quad v_m^A := A v_m; \quad v_m^B := B v_m; \quad w := \nu_0 v_m + \mu_0 v_m^B,$
7: Orthogonalize $w := w - Z_k Z_k^* w$
8: Orthogonalize $w := w - W_{m-1} w$
9: $w_m = w/\|w\|$
10: \[ M^A := \begin{bmatrix} M^A & W_{m-1}^* v_m^A \\ w_m^A v_m^T & w_m^A \\ w_m^T & w_m^B \\ w_m^T & w_m^B \end{bmatrix} ; \quad M^B := \begin{bmatrix} M^B & W_{m-1}^* v_m^B \\ w_m^B v_m^T & w_m^B \\ w_m^T & w_m^B \\ w_m^T & w_m^B \end{bmatrix} ; \]
11: Compute the QZ decomposition $M^A S^R = S^L T^A, \quad M^B S^R = S^L T^B$, such that $|T_{i,i}^A/T_{i,i}^B - \tau| \leq |T_{i,i}^A/T_{i,i+1}^B - T_{i,i}^B|$ /* Rayleigh Ritz step */
12: $u := V s_{i+1}^R; \quad p := W s_{i+1}^L; \quad u^A := V^A s_{i+1}^R; \quad u^B := V^B s_{i+1}^R; \quad \zeta = T_{i,i+1}^A; \quad \eta = T_{i,i+1}^B$;
13: $r = \eta u^A - \zeta u^B; \quad \tilde{a} = Z^* u^A; \quad \tilde{b} = Z^* u^B; \quad \tilde{r} = r - Z(\eta \tilde{a} - \zeta \tilde{b})$;
14: while $\|\tilde{r}\| < \varepsilon$ do
15: \[ R^A := \begin{bmatrix} R^A & \tilde{a} \\ 0^T & \zeta \end{bmatrix} ; \quad R^B := \begin{bmatrix} R^B & \tilde{b} \\ 0^T & \eta \end{bmatrix} ; \]
16: $Q := [Q, u]; \quad Z := [Z, p]; \quad k := k + 1$
17: if $k = k_{\text{max}}$ then return $(Q, Z, R^A, R^B)$
18: end if
19: $m := m - 1$
20: for $i = 1, \ldots, m$ do
21: $v_i := V s_{i+1}^R; \quad v_i^A := V^A s_{i+1}^R; \quad v_i^B := V^B s_{i+1}^R$;
22: $w_i := W s_{i+1}^L; \quad s_i^L := e_i$;
23: end for
24: $M^A, M^B$ is the lower $m \times m$, block of $T^A, T^B$, resp.
25: $u := u_1; \quad p := w_1; \quad u^A := v_1^A; \quad u^B := v_1^B; \quad \zeta = T_{1,1}; \quad \eta = T_{1,1}$;
26: $r = \eta u^A - \zeta u^B; \quad \tilde{a} = Z^* u^A; \quad \tilde{b} = Z^* u^B; \quad \tilde{r} = r - Z(\eta \tilde{a} - \zeta \tilde{b})$;
27: end while
28: if $m \geq m_{\text{max}}$ then
29: for $i = 2, \ldots, m_{\text{min}}$ do
30: $v_i := V s_i^R; \quad v_i^A := V^A s_i^R; \quad v_i^B := V^B s_i^R$;
31: end for
32: $M^A, M^B$ is the leading $m_{\text{min}} \times m_{\text{min}}$, block of $T^A, T^B$, resp.
33: $v_1 := u; \quad v_1^A := u^A; \quad v_1^B := u^B$;
34: end if
35: $\tilde{Q} := [Q, u]; \quad \tilde{Z} := [Z, p]$;
36: (Approximatively) solve the correction equation for $t \perp \tilde{Q}$,
37: $\quad (I - \tilde{Z})/(\eta A - \zeta B) (I - \tilde{Q} \tilde{Q}^*)$
38: end while
CHAPTER 12. THE JACOBI-DAVIDSON METHOD

For the derivative of $P$ we obtain

$$P' = \begin{bmatrix} T(\lambda) & T'(\lambda)x \\ v^* & 0 \end{bmatrix}$$

such that the Newton iteration becomes

$$(12.48) \quad \begin{pmatrix} x_{s+1} \\ \lambda_{s+1} \end{pmatrix} = \begin{pmatrix} x_s \\ \lambda_s \end{pmatrix} - \begin{bmatrix} T(\lambda_s) & T'(\lambda_s)x_s \\ v_s^* & 0 \end{bmatrix}^{-1} \begin{pmatrix} T(\lambda_s)x_s \\ v_s^*x_s - 1 \end{pmatrix}$$

or

$$(12.49) \quad T(\lambda_s)u_{s+1} = T'(\lambda_s)x_s,$$

$$\lambda_{s+1} = \lambda_s - (v_s^*x_s)/(v_s^*v_{s+1}),$$

$$x_{s+1} = C \cdot u_{s+1}.$$ 

Here, $C$ is some normalization constant. The vector $v_s$ may depend on the iteration step. It can be chosen in a number of ways. It could be constant, e.g., $v_s = e_i$. This amounts to keeping one of the entries of $x_s$ constant. Another choice is

$$v_s = T(\lambda_s)^*y_s$$

where $y_s$ is an approximation to the left eigenvector $y$.

A Jacobi-Davidson algorithm for large nonlinear eigenvalue problems is given in Algorithm 12.4. This algorithm is by Voss [14]. There are two noteworthy issues.

Algorithm 12.4 Nonlinear Jacobi–Davidson algorithm

1. Start with an initial basis $V$, $V^*V = I$; $m = 1$.
2. Determine a preconditioner $K \approx T(\sigma)$, $\sigma$ close to the first wanted eigenvalue.
3. while $m \leq$ number of wanted eigenvalues do
4. Compute an approximation to the $m$-th wanted eigenvalue $\lambda_m$ and corresponding eigenvector $s_m$ of the projected problem $V^*T(\lambda_m)Vs = 0$.
5. Determine the Ritz vector $u = Vs_m$ and the residual $r = T(\lambda_m)u$.
6. if $||r||/||u|| < \varepsilon$ then
7. Accept approximate eigenpair $(\lambda_m, u)$; $m := m + 1$;
8. Reduce the search space $V$ if necessary.
9. Choose an approximation $(\lambda_m, u)$ to the next eigenpair.
10. Compute the residual $r = T(\lambda_m)u$.
11. end if
12. $p = T'(\lambda_m)x$;
13. (Approximately) solve the correction equation for $t$,

$$(12.50) \quad (I - \frac{pu^*}{u^*u})T(\sigma)(I - \frac{uu^*}{u^*u})t = -r, \quad t \perp u.$$ 

15. Determine a new preconditioner $K \approx T(\lambda_m)$ if necessary.
16. Update the projected problem.
17. end while

1. The projected problem is the nonlinear eigenvalue problem $V^*T(\lambda_m)Vs = 0$ where $\lambda_m$ is an approximation to the wanted eigenvalue.
2. In the expansion of the search space, it is ensured that the Newton iterate is contained in the expanded search space. To this end, assume that $u$ is the Ritz vector in $R(V)$ obtained from the projected problem, $u = V\mathbf{s}$. Set $p = T'(\lambda_m)u$. We now solve the correction equation

\[(12.50) \quad (I - \frac{pu^*}{u^*p})T(\lambda_m)(I - \frac{uu^*}{u^*u})t = -r = -T(\lambda_m)u, \quad t \perp u.\]

This equation can be written as

\[T(\lambda_m)t - \alpha p = -r, \quad \alpha = \frac{1}{u^*p}u^*T(\lambda_m)t.\]

Using $T(\lambda_m)u = r$ we get

\[t = -u + \alpha T(\lambda_m)^{-1}p = -u + \alpha T(\lambda_m)^{-1}T'(\lambda_m)u.\]

$\alpha$ is determined such that $t \perp u$. Since $u \in R(V)$, we must have $T(\lambda_m)^{-1}T'(\lambda_m)u \in R([V,t])$. This ensures the quadratic convergence rate of Newton’s method.

The correction equation (12.50) in Algorithm 12.4 is typically solved to low accuracy by a preconditioned GMRES iteration where the preconditioner has the form

\[(12.51) \quad \bar{K} = (I - \frac{pu^*}{u^*p})K(I - \frac{uu^*}{u^*u}), \quad K \approx T(\sigma).\]

Solving with the preconditioner amounts to solving the equation

\[\bar{K}t = g, \quad t \perp u.\]

Bibliography

Chapter 13

Rayleigh quotient and trace minimization

13.1 Introduction

In this chapter we restrict ourselves to the symmetric/Hermitian eigenvalue problem

\[ Ax = \lambda M x, \quad A = A^*, \quad M = M^* > 0. \]

We want to exploit the property of the Rayleigh quotient that

\[ \lambda_1 = \min_{x \neq 0} \rho(x) \quad \rho(x) = \frac{x^* A x}{x^* M x}, \]

which was proved in Theorem 2.30. The basic idea of Rayleigh quotient minimization is to construct a sequence \( \{x_k\}_{k=1}^\infty \) such that \( \rho(x_{k+1}) < \rho(x_k) \) for all \( k \). The hope is that the sequence \( \{\rho(x_k)\} \) converges to \( \lambda_1 \) and by consequence the vector sequence \( \{x_k\} \) towards the corresponding eigenvector.

The procedure is as follows: For any given \( x_k \) let us choose a search direction \( p_k \), so that

\[ x_{k+1} = x_k + \delta_k p_k. \]

The parameter \( \delta_k \) is determined such that the Rayleigh quotient of the new iterate \( x_{k+1} \) becomes minimal,

\[ \rho(x_{k+1}) = \min_{\delta} \rho(x_k + \delta p_k). \]

We can write the Rayleigh quotient of the linear combination \( x_k + \delta p_k \) of two (linearly independant) vectors \( x_k \) and \( p_k \) as

\[ \rho(x_k + \delta p_k) = \frac{x_k^* A x_k + 2 \delta x_k^* A p_k + \delta^2 p_k^* A p_k}{x_k^* M x_k + 2 \delta x_k^* M p_k + \delta^2 p_k^* M p_k} \]

This is the Rayleigh quotient associated with the generalized 2 \times 2 eigenvalue problem

\[ \begin{bmatrix} x_k^* A x_k & x_k^* A p_k \\ p_k^* A x_k & p_k^* A p_k \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix} = \lambda \begin{bmatrix} x_k^* M x_k & x_k^* M p_k \\ p_k^* M x_k & p_k^* M p_k \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix}. \]
The smaller of the two eigenvalues of \((13.6)\) is the searched value \(\rho_{k+1} := \rho(x_{k+1})\) in \((13.4)\) that minimizes the Rayleigh quotient. The corresponding eigenvector is normalized such that its first component equals one\(^1\). The second component of this eigenvector is \(\delta = \delta_k\).

Inserting the solution \([1, \delta_k]^\star\) into the second line of \((13.6)\) we obtain

\[
(13.7) \quad p_k^\star(A - \rho_{k+1}M)(x_k + \delta_k p_k) = p_k^\star r_{k+1} = 0.
\]

So, the ‘next’ residual \(r_{k+1}\) is orthogonal to the actual search direction \(p_k\).

There are various ways how to choose the search direction \(p_k\). A simple way is to cycle through the coordinate vectors, a method that is called coordinate relaxation \([3]\). It cannot compete with the methods we discuss next; but it has some potential for parallelization.

\section{The method of steepest descent}

Let us make a detour to solving systems of equations

\[
(13.8) \quad Ax = b,
\]

where \(A\) is symmetric/Hermitian positive definite. Let us define the functional

\[
(13.9) \quad \varphi(x) \equiv \frac{1}{2} x^* A x - x^* b + \frac{1}{2} b^* A^{-1} b = \frac{1}{2} (Ax - b)^* A^{-1} (Ax - b).
\]

The functional \(\varphi\) is minimized at the solution \(x_\star\) of \((13.8)\). (With the above definition of \(\varphi\) the minimum is actually zero.) The negative gradient of \(\varphi\) is

\[
(13.10) \quad -\nabla \varphi(x) = b - Ax =: r(x).
\]

It is nonzero except at \(x_\star\). In the method of steepest descent \([2, 3]\) a sequence of vectors \(\{x_k\}_{k=1,2,...}\) is constructed such that the relation

\[
(13.3) \quad x_{k+1} = x_k + \delta_k p_k
\]

holds among any two consecutive vectors. The search direction \(p_k\) is chosen to be the negative gradient \(-\nabla \varphi(x_k) = r_k = b - Ax_k\). This is the direction in which \(\varphi\) decreases the most. Setting \(x_{k+1}\) as in \((13.3)\) we get

\[
0 = \frac{\partial \varphi(x_{k+1})}{\partial \delta} \bigg|_{\delta = \delta_k} = p_k^\star (Ax_k - b) + \delta_k p_k^\star A p_k = -p_k^\star r_k + \delta_k p_k^\star A p_k.
\]

Thus,

\[
(13.11) \quad \delta_k = \frac{p_k^\star r_k}{p_k^\star A p_k}
\]

which, for steepest descent, becomes

\[
(13.12) \quad \delta_k = \frac{r_k^\star r_k}{r_k^\star A r_k}
\]

\begin{remark} Notice that
\[
(13.13) \quad r_{k+1} = b - Ax_{k+1} = b - A(x_k + \delta_k p_k) = r_k - \delta_k A p_k.
\]
\end{remark}

\(^1\)The first component of this eigenvector is nonzero if it has a component in the direction of the ‘smallest eigenvector’. 
Therefore, from (13.11) we have

\[ p_k^* r_{k+1} = p_k^* r_k - \delta_k p_k^* A p_k = 0, \]

which corresponds to (13.7) in the linear system case. \( \square \)

For the eigenvalue problem we can proceed similarly by choosing \( p_k \) to be the negative gradient of the Rayleigh quotient \( \rho \),

\[ p_k = -g_k = -\nabla \rho(x_k) = -\frac{2}{x_k^* M x_k} (A x_k - \rho(x_k) M x_k). \]

Notice that \( g_k \) points in the same direction as the residual \( r_k \). (This is in contrast to the linear system case!) Since in eigenvalue problems we only care about directions we can equivalently set

\[ p_k = r_k = A x_k - \rho_k M x_k, \quad \rho_k = \rho(x_k). \]

With this choice of search direction we immediately have from (13.7) that

\[ r_k^* r_{k+1} = 0. \]

Not surprisingly, the method of steepest descent often converges slowly, as it does for linear systems. This happens if the spectrum is very much spread out, i.e., if the condition number of \( A \) relative to \( M \) is big.

### 13.3 The conjugate gradient algorithm

As with linear systems of equations a remedy against the slow convergence of steepest descent are conjugate search directions. So, let’s again first look at linear systems [5]. There, we define the search directions as\(^2\)

\[ p_k = -g_k + \beta_k p_{k-1}, \quad k > 0. \]

where the coefficient \( \beta_k \) is determined such that \( p_k \) and \( p_{k-1} \) are conjugate, i.e.,

\[ p_k^* A p_{k-1} = -g_k^* A p_{k-1} + \beta_k g_k^* A p_{k-1} = 0, \]

such that

\[ \beta_k = \frac{g_k^* A p_{k-1}}{p_{k-1}^* A p_{k-1}}. \]

Premultiplying (13.17) by \( g_k^* \) gives

\[ g_k^* p_k = -g_k^* g_k + \beta_k g_k^* p_{k-1} = -g_k^* g_k. \]

Furthermore, since \( x_k^* M x_k = 1 \) we have \( r_k = -g_k \) and

\[ 0 \overset{(13.14)}{=} g_{k+1}^* p_k \overset{(13.17)}{=} -g_{k+1}^* g_k + \beta_k g_{k+1}^* p_{k-1} \overset{(13.13)}{=} -g_{k+1}^* g_k + \beta_k g_k^* p_{k-1} + \beta_k \delta_k p_k^* A p_k. \]

\( \text{In linear systems the residual } r = b - A x \text{ is defined as the negative gradient whereas in eigenvalue computations it is defined as } r = A x - \rho(x) M x, \text{ i.e., in the same direction as the gradient. To reduce the confusion we proceed using the gradient.} \)
From (13.14) we have that $g_k^*p_{k-1} = 0$ and by construction of $p_k$ and $p_{k-1}$ being conjugate we have that $p_k^*A p_{k-1} = 0$. Thus,

$$g_{k+1}^*g_k = 0,$$

as with the method of steepest descent. Still in the case of linear systems, using these identities we find formulae equivalent to (13.19),

$$\beta_k = -\frac{g_k^*Ap_{k-1}}{p_{k-1}^*Ap_{k-1}} = -\frac{g_k^*(g_k - g_{k-1})}{g_{k-1}^*(g_k - g_{k-1})} = -\frac{g_k^*(g_k - g_{k-1})}{-p_{k-1}^*g_{k-1}}$$

(13.22)

The equivalent identities (13.19), (13.22), and (13.23) can be used to define $\beta_k$ the most economic being (13.23).

We now look at how a conjugate gradient algorithm for the eigenvalue problem can be devised. The idea is straightforward. The algorithm differs from steepest descent by the choice of the search directions that are kept conjugate, i.e., consecutive search directions satisfy $p_k^*A p_{k-1} = 0$.

The crucial difference to linear systems stems from the fact, that the functional that is to be minimized, i.e., the Rayleigh quotient, is not quadratic anymore. (In particular, there is no finite termination property.) The gradient of $\rho(x)$ is

$$g = \nabla \rho(x_k) = \frac{2}{x^*Mx} (Ax - \rho(x)Mx).$$

So, in particular, the equation (13.14), does not hold:

$$x_{k+1} = x_k + \delta_k p_k \quad \Rightarrow \quad g_{k+1} = g_k + \delta_k A p_k.$$ 

Therefore, in the context of nonlinear systems or eigenvalue problems the formulae in (13.19), (13.22), and (13.23) that define $\beta_k$ are not equivalent anymore! Feng and Owen [4] extensively compared the three formulae and found that in the context of eigenvalue problems the last identity (13.23) leads to the fastest convergence. So, we opt for this equation and define the search directions according to

$$p_0 = -g_0, \quad k = 0,$$

$$p_k = -g_k + \frac{g_k^*Mg_k}{g_{k-1}^*Mg_{k-1}}p_{k-1}, \quad k > 0,$$

(13.24)

where we have given the formulae for the generalized eigenvalue problem $Ax = \lambda Mx$. The complete procedure is given in Algorithm 13.1.

**Convergence**

The construction of Algorithm 13.1 guarantees that $\rho(x_{k+1}) < \rho(x_k)$ unless $r_k = 0$, in which case $x_k$ is the searched eigenvector. In general, i.e., if the initial vector $x_0$ has a nonvanishing component in the direction of the ‘smallest’ eigenvector $u_1$, convergence is toward the smallest eigenvalue $\lambda_1$. This assumption must also hold for vector iteration or the Lanczos algorithm.
13.3. THE CONJUGATE GRADIENT ALGORITHM

Algorithm 13.1 The Rayleigh quotient algorithm

1: Let $x_0$ be a unit vector, $\|x_0\|_M = 1$.
2: $v_0 := Ax_0, \quad u_0 := Mx_0,$
3: $\rho_0 := \frac{v_0 \cdot x_0}{u_0 \cdot x_0},$
4: $g_0 := 2(v_0 - \rho_0 u_0)$
5: while $\|g_k\| > tol$ do
6: if $k = 1$ then
7: $p_k := -g_{k-1};$
8: else
9: $p_k := -g_{k-1} + \frac{g_{k-1}^* M g_{k-1}}{g_{k-2}^* M g_{k-2}} p_{k-1};$
10: end if
11: Determine the smallest Ritz value $\rho_k$ and corresponding Ritz vector $x_k$ of $(A, M)$
12: in $\mathcal{R}(\{x_{k-1}, p_k\})$
13: $v_k := Ax_k, \quad u_k := Mx_k$
14: $\rho_k := x_k^* v_k / x_k^* u_k$
15: $g_k := 2(v_k - \rho_k u_k)$
16: end while

Let

\[
(13.25) \quad x_k = \cos \vartheta_k u_1 + \sin \vartheta_k z_k =: \cos \vartheta_k u_1 + w_k,
\]

where $\|x_k\|_M = \|u_1\|_M = \|z_k\|_M = 1$ and $u_1^* M z_k = 0$. Then we have

\[
\rho(x_k) = \cos^2 \vartheta_k \lambda_1 + 2 \cos \vartheta_k \sin \vartheta_k u_1^* A z_k + \sin^2 \vartheta_k z_k^* A z_k
= \lambda_1 (1 - \sin^2 \vartheta_k) + \sin^2 \vartheta_k \rho(z_k),
\]

or,

\[
(13.26) \quad \rho(x_k) - \lambda_1 = \sin^2 \vartheta_k (\rho(z_k) - \lambda_1) \leq (\lambda_n - \lambda_1) \sin^2 \vartheta_k.
\]

As seen earlier, in symmetric eigenvalue problems, the eigenvalues are much more accurate
than the eigenvectors.

Let us now suppose that the eigenvalues have already converged, i.e.,

\[
\rho(x_k) = \rho_k \cong \lambda_1,
\]

while the eigenvectors are not yet as accurate as desired. Then we can write

\[
(13.27) \quad r_k = (A - \rho_k M)x_k \cong (A - \lambda_1 M)x_k = \sum_{j=1}^n (\lambda_j - \lambda_1) M u_j u_j^* M x_k,
\]

which entails $u_1^* r_k = 0$ since the first summand on the right of (13.27) vanishes. From (13.25)
we have $w_k = \sin \vartheta_k z_k \perp_M u_1$. Thus,

\[
(13.28) \quad \left\{ \begin{array}{l}
(A - \lambda_1 M)w_k = (A - \lambda_1 M)x_k = r_k \perp u_1 \\
w_k^* M u_1 = 0
\end{array} \right.
\]

If $\lambda_1$ is a simple eigenvalue of the pencil $(A; B)$ then $A - \lambda_1 M$ is a bijective mapping of
$\mathcal{R}(u_1)^\perp_M$ onto $\mathcal{R}(u_1)^\perp$. If $r \in \mathcal{R}(u_1)^\perp$ then the equation

\[
(13.29) \quad (A - \lambda_1 M)w = r
\]
has a unique solution in $\mathcal{R}(u_1)^{1-M}$.

So, close to convergence, Rayleigh quotient minimization does nothing else but solving equation (13.29) by the conjugate gradient algorithm. The convergence of the Rayleigh quotient minimization is determined by the condition number of $A - \lambda_1 M$ (as a mapping of $\mathcal{R}(u_1)^{1-M}$ onto $\mathcal{R}(u_1)^{1-M}$), according to the theory of conjugate gradients for linear system of equations. This condition number is

$$\kappa_0 = K(A - \lambda_1 M)_{\mathcal{R}(u_1)^{1-M}} = \frac{\lambda_n - \lambda_1}{\lambda_2 - \lambda_1},$$

and the rate of convergence is given by

$$\sqrt{\kappa_0} - 1 \quad \sqrt{\kappa_0} + 1.$$ 

A high condition number implies slow convergence. We see from (13.31) that the condition number is high if the distance of $\lambda_1$ and $\lambda_2$ is much smaller than the spread of the spectrum of $(A; B)$. This happens more often than not, in particular with FE discretizations of PDE's.

**Preconditioning**

In order to reduce the condition number of the eigenvalue problem we change

$$Ax = \lambda M x$$

into

$$(13.32) \quad \tilde{A}\tilde{x} = \tilde{\lambda}\tilde{M}\tilde{x},$$

such that

$$\kappa(\tilde{A} - \tilde{\lambda}_1\tilde{M}) \ll \kappa(A - \lambda_1 M).$$

To further investigate this idea, let $C$ be a nonsingular matrix, and let $y = Cx$. Then,

$$\rho(x) = \frac{x^* Ax}{x^* M x} = \frac{y^* C^{-1} AC^{-1} y}{y^* C^{-1} MC^{-1} y} = \frac{y^* \tilde{A} y}{y^* \tilde{M} y} = \tilde{\rho}(y)$$

Thus,

$$\tilde{A} - \tilde{\lambda}_1\tilde{M} = C^{-1}(A - \lambda_1 M)C^{-1},$$

or, after a similarity transformation,

$$C^{-1}(\tilde{A} - \tilde{\lambda}_1\tilde{M})C = (C^* C)^{-1}(A - \lambda_1 M).$$

How should we choose $C$ to satisfy (13.33)? Let us tentatively set $C^* C = A$. Then we have

$$(C^* C)^{-1}(A - \lambda_1 M)u_j = A^{-1}(A - \lambda_1 M)u_j = (I - \lambda_1 A^{-1} M)u_j = \left(1 - \frac{\lambda_1}{\lambda_j}\right) u_j.$$

Note that

$$0 \leq 1 - \frac{\lambda_1}{\lambda_j} < 1.$$
13.4. LOCALLY OPTIMAL PCG (LOPCG)

Dividing the largest eigenvalue of $A^{-1}(A-\lambda_1M)$ by the smallest positive gives the condition number

$$(13.35) \quad \kappa_1 := \kappa \left( A^{-1}(A-\lambda_1M) \right)_{R(u)+M} = \frac{1 - \lambda_1}{1 - \lambda_2} = \frac{\lambda_2 \lambda_n - \lambda_1}{\lambda_n \lambda_2 - \lambda_1} = \frac{\lambda_2}{\lambda_n} \kappa_0.$$ 

If $\lambda_2 \ll \lambda_n$ then the condition number is much reduced. Further, $\kappa_1$ is bounded independently of $n$,

$$(13.36) \quad \kappa_1 = \frac{1 - \lambda_1/\lambda_n}{1 - \lambda_1/\lambda_2} < 1 \frac{1}{1 - \lambda_1/\lambda_2}.$$ 

So, with this particular preconditioner, $\kappa_1$ does not depend on the choice of the mesh-width $h$ in the FEM application.

The previous discussion suggests to choose $C$ in such way that $C^*C \cong A$. $C$ could, for instance, be obtained form an Incomplete Cholesky decomposition. We make this choice in the numerical example below.

Notice that the transformation $x \rightarrow y = Cx$ need not be made explicitly. In particular, the matrices $A$ and $M$ must not be formed. As with the preconditioned conjugate gradient algorithm for linear systems there is an additional step in the algorithm where the preconditioned residual is computed, see Fig. 13.1 on page 248.

13.4. LOCALLY OPTIMAL PCG (LOPCG)

The parameter $\delta_k$ in the RQMIN und (P)CG algorithms is determined such that

$$\rho(x_{k+1}) = \rho(x_k + \delta_k p_k), \quad p_k = -g_k + \alpha_k p_{k-1}$$

is minimized. $\alpha_k$ is chosen to make consecutive search directions conjugate. Knyazev [6] proposed to optimize both parameters, $\alpha_k$ and $\delta_k$, at once.

$$\rho(x_{k+1}) = \min_{\delta,\gamma} \rho(x_k - \delta g_k + \gamma p_{k-1})$$

This results in potentially smaller values for the Rayleigh quotient, as

$$\min_{\delta,\gamma} \rho(x_k - \delta g_k + \gamma p_{k-1}) \leq \min_\delta (x_k - \delta (g_k - \alpha_k p_k)).$$

Hence, Knyazev coined the notion “locally optimal”.

$\rho(x_{k+1})$ in (13.38) is the minimal eigenvalue of the $3 \times 3$ eigenvalue problem

$$(13.39) \quad \begin{bmatrix} x_k^* \\ -g_k^* \\ p_{k-1}^* \end{bmatrix} A[x_k, -g_k, p_{k-1}] \begin{bmatrix} \alpha \\ \beta \\ \gamma \end{bmatrix} = \lambda \begin{bmatrix} x_k^* \\ -g_k^* \\ p_{k-1}^* \end{bmatrix} M[x_k, -g_k, p_{k-1}] \begin{bmatrix} \alpha \\ \beta \\ \gamma \end{bmatrix}$$

We normalize the eigenvector corresponding to the smallest eigenvalue such that its first component becomes 1,

$$[1, \delta_k, \gamma_k] := [1, \beta/\alpha, \gamma/\alpha].$$

These values of $\delta_k$ and $\gamma_k$ are the parameters that minimize the right hand side in (13.38). Then we can write

$$x_{k+1} = x_k - \delta_k g_k + \gamma_k p_{k-1} = x_k + \delta_k (-g_k + (\gamma_k/\delta_k)p_{k-1}) = x_k + \delta_k p_k.$$ 

We can consider $x_{k+1}$ as having been obtained by a Rayleigh quotient minimization from $x_k$ along $p_k = -g_k + (\gamma_k/\delta_k)p_{k-1}$. Notice that this direction is needed in the next iteration step. (Otherwise it is not of a particular interest.)

Figure 13.2: MATLAB code LOPCG: Locally Optimal Preconditioned Conjugate Gradient algorithm
13.5 The block Rayleigh quotient minimization algorithm (BRQMIN)

The above procedures converge very slowly if the eigenvalues are clustered. Hence, these methods should be applied only in blocked form.

13.6 The locally-optimal block preconditioned conjugate gradient method (LOBPCG)

In BRQMIN the Rayleigh quotient is minimized in the 2q-dimensional subspace generated by the eigenvector approximations $X_k$ and the search directions $P_k = -H_k + P_{k-1}B_k$, where the $H_k$ are the preconditioned residuals corresponding to $X_k$ and $B_k$ is chosen such that the block of search directions is conjugate. Instead, Knyazev [6] suggests that the space for the minimization be augmented by the $q$-dimensional subspace $R(H_k)$. The resulting algorithm is deemed ‘locally-optimal’ because $\rho(x)$ is minimized with respect to all available vectors.

Algorithm 13.2 The locally-optimal block preconditioned conjugate gradient method (LOBPCG) for solving $Ax = \lambda Mx$ with preconditioner $N$ of [1]

1: Choose random matrix $X_0 \in \mathbb{R}^{n \times q}$ with $X_0^T M X_0 = I_q$. Set $Q := [ ]$.
2: Compute $(X_0^T A X_0) S_0 = S_0 \Theta_0$ where $S_0^T S_0 = I_q$, $\Theta_0 := \text{diag}(\vartheta_1, \ldots, \vartheta_q)$, $\vartheta_1 \leq \ldots \leq \vartheta_q$.
3: $X_0 := X_0 S_0$; $R_0 := A X_0 - M X_0 \Theta_0$; $P_0 := [ ]$; $k := 0$.
4: while rank$(Q) < p$ do
5: Solve the preconditioned linear system $N H_k = R_k$.
6: $H_k := H_k - Q (Q^T M H_k)$.
7: $A := [X_k, H_k, P_k] M [X_k, H_k, P_k]$.
8: $M := [X_k, H_k, P_k]^T M [X_k, H_k, P_k]$.
9: Compute $\tilde{A} \tilde{S}_k = \tilde{M} \tilde{S}_k \tilde{\Theta}_k$ /* (Spectral decomposition) */ where $\tilde{S}_k^T \tilde{M} \tilde{S}_k = I_{3q}$, $\tilde{\Theta}_k := \text{diag}(\vartheta_1, \ldots, \vartheta_{3q})$, $\vartheta_1 \leq \ldots \leq \vartheta_{3q}$.
10: $S_k := \tilde{S}_k [e_1, \ldots, e_q]$, $\Theta := \text{diag}(\vartheta_1, \ldots, \vartheta_q)$.
11: $P_{k+1} := [H_k, P_k] \tilde{S}_{k,2}$; $X_{k+1} := X_k S_{k,1} + P_{k+1}$.
12: $R_{k+1} := A X_{k+1} - M X_{k+1} \Theta_k$.
13: $k := k + 1$.
14: for $i = 1, \ldots, q$ do
15: /* (Convergence test) */
16: if $\|R_{k+1} e_i\| < \text{tol}$ then
17: $Q := [Q, X_k e_i]$; $X_k e_i := t$, with $t$ a random vector.
18: $M$-orthonormalize the columns of $X_k$.
19: end if
20: end for
21: end while

If $d_j = [d_{1j}^T, d_{2j}^T, d_{3j}^T]^T$, $d_{ij} \in \mathbb{R}^q$, is the eigenvector corresponding to the $j$-th eigenvalue of (13.1) restricted to $R([X_k, H_k, P_{k-1}])$, then the $j$-th column of $X_{k+1}$ is the corresponding
13.7. A NUMERICAL EXAMPLE

Ritz vector

\[ X_{k+1} e_j := [X_k, H_k, P_{k-1}] d_j = X_k d_{1j} + P_k e_j, \]

with

\[ P_k e_j := H_k d_{2j} + P_{k-1} d_{3j}. \]

Notice that \( P_0 \) is an empty matrix such that the eigenvalue problem in step (8) of the locally-optimal block preconditioned conjugate gradient method (LOBPCG), displayed in Algorithm 13.2, has order 2\( q \) only for \( k = 0 \).

The algorithm as proposed by Knyazev [6] was designed to compute just a few eigenpairs and so a memory efficient implementation was not presented. For instance, in addition to \( X_k, R_k, H_k, P_k \), the matrices \( MX_k, MH_k, MP_k \) and \( AX_k, AH_k, AP_k \) are also stored. The resulting storage needed is prohibitive if more than a handful of eigenpairs are needed.

A more memory efficient implementation results when we iterate with blocks of width \( q \) in the space orthogonal to the already computed eigenvectors. The computed eigenvectors are stored in \( Q \) and neither \( MQ \) nor \( AQ \) are stored. Hence only storage for \((p + 10q)n + O(q^2)\) numbers is needed.

Here, the columns of \([X_k, H_k, P_k]\) may become (almost) linearly dependent leading to ill-conditioned matrices \( \tilde{A} \) and \( \tilde{M} \) in step (9) of the LOBPCG algorithm. If this is the case we simply restart the iteration with random \( X_k \) orthogonal to the computed eigenvector approximations. More sophisticated restarting procedures that retain \( X_k \) but modify \( H_k \) and/or \( P_k \) were much less stable in the sense that the search space basis again became linearly dependent within a few iterations. Restarting with random \( X_k \) is a rare occurrence and in our experience, has little effect on the overall performance of the algorithm.

13.7 A numerical example

We again look at the determination the acoustic eigenfrequencies and modes in the interior of a car, see section 1.6.3. The computations are done with the finest grid depicted in Fig. 1.9. We compute the smallest eigenvalue of the problem with RQMIN and LOPCG, with preconditioning and without. The preconditioner we chose was the incomplete Cholesky factorization without fill-in, usually denoted IC(0). This factorization is implemented in the MATLAB routine `ichol`.

The convergence histories in Figure 13.3 for RQMIN and LOPCG show that preconditioning helps very much in reducing the iteration count.

In Figure 13.4 the convergence histories of LOBPCG for computing ten eigenvalues is shown. In 43 iteration steps all ten eigenvalues have converged to the desired accuracy ($\varepsilon = 10^{-5}$). Clearly, the iteration count has been decreased drastically. Note however, that each
13.8. Trace minimization

Iteration step requires solving ten systems of equation resulting in 430 system solves. (In fact, if converged eigenvectors are locked, only 283 systems had to be solved.) Nevertheless, when comparing with Fig. 13.3 one should remember that in the LOBPCG computation ten eigenpairs have been computed. If a single eigenpair is required then a blocksize of 10 is too big, but a smaller blocksize may reduce the execution time. If a small number of eigenvalues is desired then a blocksize equal or slightly bigger than this number is certainly advantageous. Not that in step (5) of Algorithm 13.2 $q$ linear systems of equations are solved concurrently. An efficient implementation accesses the preconditioner $N$ only once. The MATLAB code does this naturally. A parallel implementation of LOBPCG can be found in the software package Block Locally Optimal Preconditioned Eigenvalue Xolvers (BLOPEX) [7].

13.8 Trace minimization

Remember that the \textbf{trace} of a matrix $A \in \mathbb{F}^{n \times n}$ is defined to be the sum of its diagonal elements. Similar matrices have equal trace. Hence, by the spectral theorem 2.14, we have

\begin{equation}
\text{trace}(A) = \sum_{i=1}^{n} a_{ii} = \sum_{i=1}^{n} \lambda_i.
\end{equation}

The following theorem [11] generalizes the trace theorem 2.33 for the generalized eigenvalue problem

\begin{equation}
Ax = \lambda Mx, \quad A = A^*, \quad M = M^* > 0.
\end{equation}

\textbf{Theorem 13.1} (Trace theorem for the generalized eigenvalue problem) Let $A$ and $M$ be as in (13.1). Then,

\begin{equation}
\lambda_1 + \lambda_2 + \cdots + \lambda_p = \min_{X \in \mathbb{F}^{n \times p}, \ X^*MX = I_p} \text{trace}(X^*AX)
\end{equation}
where $\lambda_1, \ldots, \lambda_n$ are the eigenvalues of problem (13.1). Equality holds in (13.43) if and only if the columns of the matrix $X$ that achieves the minimum span the eigenspace corresponding to the smallest $p$ eigenvalues.

Sameh and coworkers [11, 10] suggested an algorithm to exploit this property of the trace, following the lines of Rayleigh quotient minimization. Let $X_k \in \mathbb{F}^{n \times p}$ with $X_k^* M X_k = I_p$ and

$$X_k^* A X_k = \Sigma_k = \text{diag}(\sigma_1^{(k)}, \ldots, \sigma_p^{(k)}).$$

We want to construct the next iterate $X_{k+1}$ by setting

$$X_{k+1} = (X_k - \Delta_k) S_k$$

such that

$$(13.45) \quad X_{k+1}^* M X_{k+1} = I_p,$$

$$(13.46) \quad X_{k+1}^* A X_{k+1} = \Sigma_{k+1} = \text{diag}(\sigma_1^{(k+1)}, \ldots, \sigma_p^{(k+1)}),$$

$$(13.47) \quad \text{trace}(X_{k+1}^* A X_{k+1}) < \text{trace}(X_k^* A X_k).$$

$S_k$ in (13.44) is needed to enforce the orthogonality of $X_{k+1}$. We choose the correction $\Delta_k$ to be orthogonal to $X_k$,

$$\Delta_k^* M X_k = 0.$$  (13.48)

Similarly as in Jacobi–Davidson [13] this choice of $\Delta_k$ is no loss of generality. We first assume that we have found the $\Delta_k$ that minimizes

$$\text{trace}((X_k - \Delta_k)^* A (X_k - \Delta_k))$$

under the constraint (13.48). Let $Z_{k+1} = X_k - \Delta_k$ be the solution of (13.49). Then, by construction,

$$\text{trace}(Z_{k+1}^* A Z_{k+1}) \leq \text{trace}(X_k^* A X_k).$$
Furthermore,
\[ Z_{k+1}^*MZ_{k+1} = X_k^*MX_k + \Delta_k^*M\Delta_k \geq X_k^*MX_k = I_p. \]

From this it follows that \( Z_{k+1} \) has maximal rank and that all eigenvalues of \( Z_{k+1}^*MZ_{k+1} \) are \( \geq 1 \). Therefore, the spectral decomposition of \( Z_{k+1}^*MZ_{k+1} \) can be written in the form
\[ Z_{k+1}^*MZ_{k+1} = UD^2U^*, \quad U^*U = I_p, \quad D = \text{diag}(\delta_1, \ldots, \delta_p), \quad \delta_i \geq 1. \]

This implies that the columns of \( Z_{k+1}UD^{-1} \) are \( M \)-orthogonal. Let the spectral decomposition of \( D^{-1}U^*Z_{k+1}AZ_{k+1}UD^{-1} \) be given by
\[ D^{-1}U^*Z_{k+1}AZ_{k+1}UD^{-1} = V\Sigma_{k+1}V^*, \quad V^*V = I_p. \]

Then,
\[
\begin{align*}
(13.50) \quad & V^*D^{-1}U^*Z_{k+1}MZ_{k+1}UD^{-1}V = I_p, \\
(13.51) \quad & V^*D^{-1}U^*Z_{k+1}AZ_{k+1}UD^{-1} = \Sigma_{k+1}.
\end{align*}
\]

So, if we have found \( Z_{k+1} = X_k - \Delta_k \) then \( S_k \) in (13.44) is given by
\[ S_k = UD^{-1}V. \]

Thus, with \( X_{k+1} = Z_{k+1}S_k \) we have
\[
\text{trace}(X_{k+1}^*AX_{k+1}) = \text{trace}(\Sigma_{k+1}) = \text{trace}(V^*D^{-1}U^*Z_{k+1}AZ_{k+1}UD^{-1}V) = \text{trace}(D^{-1}U^*Z_{k+1}AZ_{k+1}UD^{-1}) = \sum_{i=1}^p \frac{w_{ii}}{\delta_i^2} \\
\leq \sum_{i=1}^p w_{ii} = \text{trace}(U^*Z_{k+1}AZ_{k+1}U) \leq \text{trace}(X_k^*AX_k)
\]

Equality can only hold if \( \Delta_k = 0 \).

To solve the minimization problem (13.49) we write
\[
\text{trace}((X_k - \Delta_k)^*A(X_k - \Delta_k)) = \sum_{i=1}^p e_i^*(X_k - \Delta_k)^*A(X_k - \Delta_k)e_i = \sum_{i=1}^p (x_i - d_i)^*A(x_i - d_i)
\]

where \( x_i = X_k e_i \) and \( d_i = \Delta_k e_i \). Interestingly, these are \( p \) individual minimization problems, one for each \( d_i \)!

\[
(13.52) \quad \text{Minimize} \quad (x_i - d_i)^*A(x_i - d_i) \quad \text{subject to} \quad X_k^*Md_i = 0, \quad i = 1, \ldots, p.
\]
To solve (13.52) we define the functional 

\[ f(d, l) := (x_i - d)^* A(x_i - d) + l^* X_k^* M d. \]

Here, the vector \( l \) contains the Lagrange multipliers. A necessary condition for \( d \) to be a solution of (13.52) is

\[ \partial_d f = 0 \iff A(x_i - d) + MX_k l = 0, \]
\[ \partial_l f = 0 \iff X_k^* M d = 0. \]

In matrix form this is

\[
\begin{bmatrix}
    A & MX_k \\
    X_k^* M & O
\end{bmatrix}
\begin{bmatrix}
    d^T \\
    1
\end{bmatrix}
=
\begin{bmatrix}
    Ax_i \\
    0
\end{bmatrix}.
\]

We can collect all \( p \) equations in one,

(13.53)

\[
\begin{bmatrix}
    A & MX_k \\
    X_k^* M & O
\end{bmatrix}
\begin{bmatrix}
    \Delta_k \\
    L
\end{bmatrix}
=
\begin{bmatrix}
    AX_k \\
    O
\end{bmatrix}.
\]

Using the \( LU \) factorization

\[
\begin{bmatrix}
    A & MX_k \\
    X_k^* M & O
\end{bmatrix}
= \begin{bmatrix}
    I & 0 \\
    X_k^* MA^{-1} & I
\end{bmatrix}
\begin{bmatrix}
    A & MX_k \\
    O & -X_k^* MA^{-1} MX_k
\end{bmatrix}
\]

we obtain

\[
\begin{bmatrix}
    A & MX_k \\
    O & -X_k^* MA^{-1} MX_k
\end{bmatrix}
\begin{bmatrix}
    \Delta_k \\
    L
\end{bmatrix}
= \begin{bmatrix}
    I & 0 \\
    -X_k^* MA^{-1} & I
\end{bmatrix}
\begin{bmatrix}
    AX_k \\
    O
\end{bmatrix}
= \begin{bmatrix}
    AX_k \\
    -X_k^* MX_k
\end{bmatrix}.
\]

Since \( X_k^* MX_k = I_p \), \( L \) in (13.53) becomes

\[ L = (X_k^* MA^{-1} MX_k)^{-1}. \]

Multiplying the first equation in (13.53) by \( A^{-1} \) we get

\[ \Delta_k + A^{-1} MX_k L = X_k, \]

such that

\[ Z_{k+1} = X_k - \Delta_k = A^{-1} MX_k L = A^{-1} MX_k (X_k^* MA^{-1} MX_k)^{-1}. \]

Thus, one step of the above trace minimization algorithm amounts to one step of subspace iteration with shift \( \sigma = 0 \). This proves convergence of the algorithm to the smallest eigenvalues of (13.1). Remember the similar equation (12.13) for the Jacobi–Davidson iteration and Remark 12.2.

Let \( P \) be the orthogonal projection onto \( \mathcal{R}(MX_k)^\perp \),

(13.54) \[ P = I - (MX_k)((MX_k)^*(MX_k))^{-1}(MX_k)^* = I - MX_k(X_k^* M^2 X_k)^{-1} X_k^* M. \]

Then the linear systems of equations (13.53) and

(13.55) \[ P A P \Delta_k = P A X_k, \quad X_k^* M \Delta_k = 0, \]

are equivalent, i.e., they have the same solution \( \Delta_k \). In fact, let \( \begin{bmatrix} \Delta_k \\ L \end{bmatrix} \) be the solution of (13.53). Then, from \( X_k M \Delta_k = 0 \) we get \( P \Delta_k = \Delta_k \). Equation (13.55) is now obtained

\[ \]
### Algorithm 13.3 Trace minimization algorithm to compute \( p \) eigenpairs of \( Ax = \lambda Mx \)

1. Choose random matrix \( V_1 \in \mathbb{R}^{n \times q} \) with \( V_1^T MV_1 = I_q \), \( q \geq p \).
2. for \( k = 1, 2, \ldots \) until convergence do
   3. Compute \( W_k = AV_k \) and \( H_k = V_k^* W_k \).
   4. Compute spectral decomposition \( H_k = U_k \Theta_k U_k^* \), with \( \Theta_k = \text{diag}(\vartheta_1^{(k)}, \ldots, \vartheta_q^{(k)}) \), \( \vartheta_1^{(k)} \leq \ldots \leq \vartheta_q^{(k)} \).
   5. Compute Ritz vectors \( X_k = V_k U_k \) and residuals \( R_k = W_k U_k - MX_k \Theta_k \).
   6. For \( i = 1, \ldots, q \) solve approximately
      \[
      P(A - \sigma_i^{(k)} M) Pd_i^{(k)} = Pr_i, \quad d_i^{(k)} \perp_M X_k
      \]
      by some modified PCG solver.
   7. Compute \( V_{k+1} = [X_k - \Delta_k, R_k], \Delta_k = d_1^{(k)}, \ldots, d_q^{(k)} \), by a \( M \)-orthogonal modified Gram-Schmidt procedure.
8. end for

By multiplying the first equation in (13.53) by \( P \). On the other hand, let \( \Delta_k \) be the solution of (13.55). Since \( P(A \Delta_k - AX_k) = 0 \) we must have \( A \Delta_k - AX_k = MX_k L \) for some \( L \). As \( X_k M \Delta_k = 0 \) we get \( P \Delta_k = \Delta_k \) and thus the first equation in (13.53).

As \( PAP \) is positive semidefinite, equation (13.55) is easier to solve than equation (13.53) which is an indefinite system of equations. (13.55) can be solved by the (preconditioned) conjugate gradient method (PCG). The iteration has to be started by a vector \( z_0 \) that satisfies the constrains \( X_k^* M z_0 = 0 \). A straightforward choice is \( z_0 = 0 \).

Table 13.1: The basic trace minimization algorithm (Algorithm 13.3). The inner systems are solved by the CG scheme which is terminated such that the 2-norm of the residual is reduced by a specified factor. The number of outer iterations (#its) and the number of multiplications with matrix \( A \) (A mults) are listed for different residual reduction factors.

In practice, we do not solve the \( p \) linear systems
\[
(13.56) \quad P(A - \sigma_i^{(k)} M) Pd_i^{(k)} = Pr_i, \quad d_i^{(k)} \perp_M X_k
\]
to high accuracy. In Table 13.1 the number of outer iterations (#its) are given and the number of multiplications of the matrix \( A \) with a vector for various relative stopping criteria for the inner iteration (reduction factor) [10].

**Acceleration techniques**

Sameh & Tong [10] investigate a number of ways to accelerate the convergence of the trace minimization algorithm 13.3.

1. **Simple shifts.** Choose a shift \( \sigma_1 \leq \lambda_1 \) until the first eigenpair is found. Then proceed with the shift \( \sigma_2 \leq \lambda_2 \) and lock the first eigenvector. In this way PCG can be used to solve the linear systems as before.
CHAPTER 13. RAYLEIGH QUOTIENT AND TRACE MINIMIZATION

2. **Multiple dynamic shifts.** Each linear system (13.56) is solved with an individual shift. The shift is ‘turned on’ close to convergence. Since the linear systems are indefinite, PCG has to be adapted.

3. **Preconditioning.** The linear systems (13.56) can be preconditioned, e.g., by a matrix of the form $M = CC^*$ where $CC^* \approx A$ is an incomplete Cholesky factorization. One then solves

\[
\tilde{P}(\tilde{A} - \sigma_i^{(k)} \tilde{M}) \tilde{P} \tilde{d}_i^{(k)} = \tilde{P} \tilde{r}_i, \quad \tilde{X}_k^* \tilde{M} \tilde{d}_i^{(k)} = 0
\]

with $\tilde{A} = C^{-1}AC^{-*}, \tilde{M} = C^{-1}MC^{-*}, \tilde{d}_i^{(k)} = C^*d_i^{(k)}, \tilde{X}_k = C^*X_k, \tilde{x}_i^{(k)} = C^*x_i^{(k)},$ and $\tilde{P} = I - \tilde{M} \tilde{X}_k (\tilde{X}_k^* \tilde{M}^2 \tilde{X}_k)^{-1} \tilde{X}_k^* \tilde{M}$.

In Table 13.2 results are collected for some problems in the Harwell–Boeing collection [10]. These problems are difficult because the gap ratios for the smallest eigenvalues are extremely small due to the huge span of the spectra. Without preconditioning, none of these problems can be solved with a reasonable cost. In the experiments, the incomplete Cholesky factorization (IC(0)) of $A$ was used as the preconditioner for all the matrices of the form $A - \sigma B$.

Table 13.2: Numerical results for problems from the Harwell–Boeing collection with four processors (reproduced from [10])

The Davidson-type trace minimization algorithm with multiple dynamic shifts works better than the block Jacobi–Davidson algorithm for three of the five problems. For the other two, the performance for both algorithms is similar.

**Bibliography**
